Changes in lucerne pollinating wild bee assemblages in Hungary from the pre-pesticide era to 2007

With 4 tables

LAJOS TANÁCS, PÁL BENEDEK and LÁSZLÓ MÓCZÁR

Summary

As a result of five national surveys in Hungary from the pre-pesticide era up to recent years (1954-1956, 1967-1968, 1971-1972, 1998-2002, 2003-2007), rich wild bee assemblages were recorded at flowering lucerne fields. 196 bee species were detected, including the honey bee. Comparing the structure of wild bee assemblages visiting flowering lucerne fields in Hungary, it can be concluded that their species composition changed considerably in this period of rather more than fifty years. First, a dramatic decline of *Eucera* and *Tetralonia* species of medium flight periods was detected from the pre-pesticide era (1954-1956) up to the pesticide era in Hungary (1967-1968). This situation remained unchanged up to the present time. The main reason for this is the more widespread use of herbicides on arable land, as well as mechanical weed control becoming a regular practice along roadsides, ditches and in fields of cultivated crops. The decline of non-cultivated ruderal plots in cultivated crop fields and nearly-natural areas at the expense of more intense agricultural land use are also responsible for the considerable changes in the composition of wild bee assemblages. At the same time, the ratio of some mid summer wild bee species of short flight period increased considerably (*Melitta leporina* (Pz.), *Rhophitoides canus* Ev.) from the fifties up to the late sixties, because the acreage of lucerne production increased in this period and the size of individual lucerne fields was greatly enlarged, providing greater pollen resources and nesting possibilities for these specialist bees. This tendency, however, reversed in the past decade because lucerne production greatly decreased as a result of a greatly reduced demand for fodder legumes in Hungary. In recent years a new trend seems to have arisen, with a rapid increase in the dominance of bumble bees (*Bombus* species) and accompanying reduction in abundance of other groups of wild bee.

Zusammenfassung

Als Ergebnis von fünf landesweiten Erhebungen seit der Zeit vor der Pestizid-Ära bis in die Gegenwart (1954-1956, 1967-1968, 1971-1972, 1998-2002, 2003-2007) wurden artenreiche Wildbienenzönosen an blühenden Luzernefeldern ermittelt. 196 Bienarten, einschließlich der Honigbiene, wurden nachgewiesen. Aus dem Vergleich der Artenspektren der Blütenbesucher kann geschlossen werden, dass sich die Wildbienenzönosen in diesem Zeitabschnitt von etwas mehr als fünfzig Jahren deutlich verändert haben. Zunächst wurde ein dramatischer Rückgang von *Eucera*- und *Tetralonia*-Arten mit mittellanger Flugperiode zwischen der Zeit vor der Pestizid-Ära (1954-1956) bis in die Pestizid-Ära in Ungarn (1967-1968) festgestellt. Dieser Zustand blieb bis zur heutigen Zeit unverändert. Die Hauptursachen für diese Entwicklung sind der verstärkte Einsatz von Pestiziden auf Kulturböden sowie das Aufkommen einer regelmäßigen mechanischen Unkrautbekämpfung entlang von Straßen, Gräben und auf Kulturländern. Ferner ist der Rückgang unkultivierter Flächen in Feldern und naturnahen Gebieten zugunsten einer intensiveren Agrarlandnutzung eine weitere Ursache für die bedeutende Veränderung in den Wildbienenzönosen. Gleichzeitig ist der Anteil von Hochsommer-Wildbienarten mit kurzer Flugperiode (*Melitta leporina* (Pz.), *Rhophitoides canus* Ev.) während der 50er bis späten 60er Jahren beträchtlich größer geworden, weil sowohl die Anbaufläche für Luzerne als auch die Schlaggröße der Luzerne-Felder erheblich vergrößert worden waren. Dadurch wurden

die Pollen-Ressourcen und Nistmöglichkeiten für diese spezialisierten Bienen vermehrt. Jedoch kehrt sich diese Tendenz im letzten Jahrzehnt um, weil die Nachfrage nach Futter-Leguminosen stark nachließ. In den letzten Jahren scheint sich ein neuer Trend entwickelt zu haben: die Dominanz von Hummeln (*Bombus*-Arten) hat stark zugenommen, die Abundanz von anderen Wildbienengruppen hat dagegen abgenommen.

Key words

wild bees, changing dominance, effect of changing agriculture

Introduction

To preserve diversity of indigenous wild bee fauna is a vital element in sustainable agriculture (WILLIAMS 1996, EARDLEY 2001, RAW 2001). Seed production of lucerne (alfalfa) is also dependent on the pollinating activity of bees (BOHART 1957, 1960; FREE 1970, 1993; WILLIAMS 1996).

It was in the pre-pesticide era in the mid 1950s when a detailed survey on the specific structure of lucerne pollinating Apoidea began in Hungary (MÓCZÁR & BÖJRTÖS 1957, MÓCZÁR 1959a, 1959b, 1961a, 1961b). In the late 1960s, after the pesticide usage had become a general practice, a second national survey was made in Hungary (BENEDEK 1967, 1968a, 1968b, 1969a, 1969b, 1970). In the 1970s a third survey was made at Great Hungarian Plain (TANÁCS 1972, 1974, 1977). For detecting the possible changes in wild bee assemblages there were two more national surveys organized in the period of 1998-2002 and 2003-2007 by the authors of this paper (TANÁCS & BENEDEK 2004, and TANÁCS, BENEDEK & BODNÁR 2008).

The wild bee fauna of the Carpathian Basin consists of approximately 700 species of which 170 species have been registered at lucerne fields in flower (MÓCZÁR 1959a, 1959b, 1961a, 1961b, BENEDEK 1967, 1968a, 1968b, 1969a, 1969b, 1972, TANÁCS 1972, 1974, 1977, TANÁCS & BENEDEK 2004, TANÁCS, BENEDEK & BODNÁR 2008).

Methods

In the past 54 years two methods were applied to collect lucerne visiting wild bees. MÓCZÁR and BÖJRTÖS in 1954-1956, and TANÁCS in 1971-1972 used MÓCZÁR's "track method" during their collections (MÓCZÁR & BÖJRTÖS 1957). They marked out 10 m² plots with string and 4 poles at flowering lucerne fields and they divided each plot to ten 1 m long subplots. They observed each 1 m² subplots for 30 seconds collecting all wild bee individuals flying in and visiting lucerne flowers at the subplots with an entomologist's net. Ten 10 m² plots were taken diagonally at each lucerne field examined and so 100 m² area was inspected at each lucerne field surveyed. This method was applied at a number of lucerne fields in bloom between 9 am and 4 pm daily, on days favouring for bee activity.

Benedek used a "simple track method" (BENEDEK 1967). He was walking slowly along a 100 m long and 50 cm wide track within flowering lucerne fields for 50 minutes (120 m per hour) looking steadily in a 45 degree angle. Each wild bee on wing at lucerne flowers got to be collected with an entomologist's net in the track observed. The method was applied between 9 am and 4 pm daily on several days with favourable or acceptable weather for bee activity.

Most lucerne fields were of 1 to 20 or sometimes some 50 ha large but occasionally there were some fields with an area of 100-150. Very large fields were divided into two or three parts and we made two or three collections daily.

The collected bees were prepared that day and were identified later. The dominance conditions of the wild bee assemblages can be seen from the percentage of the wild bee species collected. The structure of the assemblages collected in the five survey periods was estimated one by one. In addition to the dominance of wild bee species collected in the pre-pesticide and pesticide era also their geographical distribution and the climatic demands were analysed. Also the distribution of wild bees according to their seasonal flight periods was evaluated (types of seasonal flight periods were treated according to BENEDEK (1968a)).

Material

MÓCZÁR and his co-workers in 1954-1956 collected 8 168 wild bees of 89 species during their research made at 27 lucerne fields in 274 collecting at 4 regions of Hungary (counties Baranya, Fejér, Szolnok, Békés).

BENEDEK and his co-workers collected 13 672 wild bees of 66 species in the fields of 117 settlements (same number of collecting) in Hungary during their surveys in 1967-1968 at 4 regions (counties Békés, Hajdú-Bihar, Jász-Nagykun-Szolnok and Győr-Moson-Sopron).

TANÁCS collected 1 145 wild bees of 68 species in sandy and heavy soil lucerne fields on the southern part of the Great Hungarian Plain (counties Csongrád County) in 38 days during the same number of collecting in 1971-1972.

TANÁCS and BENEDEK collected 3 184 wild bees of 88 species in 59 days during 86 collecting in the period of 1998-2002 at 5 regions in Hungary (counties Békés, Csongrád, Győr-Moson-Sopron, Jász-Nagykun-Szolnok and Hajdú-Bihar).

During the research of TANÁCS and BENEDEK in 2003-2007 there were 5 735 wild bees collected of 111 species near 77 settlements at the same 5 regions as during their previous survey, during 442 collecting.

So the total number of wild bees collected was 31 904 specimens that was the result of 957 individual collecting.

Results

As a result of the five series of national surveys in the past 54 years in Hungary as much as 196 Apoidea species including honey bees were identified at flowering lucerne fields (Table 1).

Evaluating the dominance of the species detected (Table 2), in the pre-pesticide era in 1954-1956 *Eucera clypeata* Er. was found to be dominant during all over Hungary (20.46 %), while *Melitta leporina* (Pz.) (18.86 %) and *Andrena ovatula* (K.) (16.90 %) were subdominant.

In 1967-1968 *Melitta leporina* (Pz.) (20.15 %) was dominant all over Hungary, while *Bombus terrestris* (L.) (15.22 %), *Andrena ovatula* (K.) (14.13 %), *Lasioglossum malachurum* (K.) (13.04 %) and *Rhophitoides canus* Ev. (12.12 %) were subdominant species (Table 2).

In 1971-1972 the *Melitta leporina* (Pz.) (13.45 %) was dominant during the collections on the Southern region of the Great Hungarian Plain, while *Andrena ovatula* (K.) (12.14 %) and *Melitturga clavicornis* LATR. (8.12 %) were subdominant species (Table 2).

Between 1998-2002 *Melitta leporina* (Pz.) (15.73 %) and *Rhophitoides canus* Ev. (14.26 %) were found to be co-dominant, while *Bombus lapidarius* (L.) (9.45 %), *Halictus simplex* (BLÜTHGEN)

(8.23 %), *Andrena flavipes* Pz. (7.54 %), *Bombus terrestris* (L.) (6.88 %) and *Bombus humilis* Illiger (6.60 %) were subdominant.

In 2003-2007 *Bombus terrestris* (L.) (18.62 %) and *Bombus lapidarius* (L.) (16.98 %) were co-dominant species during the collections all over Hungary, while *Andrena flavipes* Pz. (10.80 %), *Melitta leporina* (Pz.) (6.94 %) and *Andrena labialis* (K.) (6.54 %) were subdominant species.

Evaluating the composition of wild bee assemblages at flowering lucerne fields in Hungary during past 54 years we found that definite changes were going on in the structure and the dominance ratios of the species. In the pre-pesticide era (1954-1956) *Eucera clypeata* Er. with medium flight period made up over one fifth of the wild bee assemblages at flowering lucerne fields. The ratio of this taxon as well as of all the other *Eucera* and *Tetralonia* species of medium flight period drastically declined later on. The dominance of *Melitta leporina* Pz., being oligolectes at Fabaceae and closely adapted to the genera *Medicago*, increased in number in the 1960s and 70s. The dominance of lucerne visiting *Bombus* species within the assemblages, on the other hand, grew considerably due to their great density in the past 10 years. The latest collecting during the past 10 years seem to prove that also *Andrena*, *Halictus*, *Lasioglossum* and *Megachile* species have remained abundant within the wild bee assemblages at lucerne fields.

In all the five survey periods, the ratio of Palaearctic bees were the greatest (Table 3). The percentage of European species was also significant within the wild bee assemblages (Table 3). The Mediterranean species in the overall estimation (Ponto-Mediterranean, North Mediterranean, Holomediterranean) showed the greatest number within the wild bee assemblages (33.34 - 39.71 %). When estimating the zoogeographical distribution of wild bee species recorded at flowering lucerne fields we cannot observe clear differences between the pre-pesticide and pesticide eras. One important fact is, however, that in Hungary the dominance and especially the density of *Eucera* and *Tetralonia* species with Southern-origin declined significantly at lucerne fields during the past 54 years in the pesticide era.

As far as the climatic demands of wild bees is concerned (Table 4) in the pre-pesticide era during the collecting in 1954-1956 the euryoecious eremophilous species were the most numerous within the assemblages (42.70 %) followed by the hypereuryoecious intermediary species (29.21 %). The percentage of the euryoecious hylophilous species was the lowest (10.11 %) within the assemblages. In the period of 1967-1968 the ratio of euryoecious eremophilous species was 48.48 % while that of the hypereuryoecious intermediary species was 24.24 % within the assemblages. The number of stenoecious eremophilous species (10.61 %), was the lowest (Table 4). Also the euryoecious eremophilous species had the most significant ratio in 1971-1972 (42.65 %), followed by hypereuryoecious intermediary species (30.88 %). Here the ratio of the euryoecious hylophilous (8.82 %) species was the lowest (Table 4). During the examinations in 1998-2002 the euryoecious eremophileus species (37.50 %) and the hypereuryoecious intermediary group (34.09 %) were dominant and the lowest ratio (12.50 %) was that of the euryoecious hylophilous species (Table 4). During 2003-2007 the dominant group consisted of the euryoecious eremophilous species 43.24 % followed by the hypereuryoecious intermediary group 28.83 % while the euryoecious hylophilous species (11.71 %) had the lowest percentage (Table 4).

Discussion and conclusions

Comparing the specific structure of wild bees visiting flowering lucerne field in Hungary in past 54 years it can be concluded that the composition of the wild bee assemblages changed considerably. First a dramatic decline of *Eucera* and *Tetralonia* species of medium flight periods was

detected from the pre-pesticide era (MÓCZÁR 1957, 1959a, 1959b) up to the pesticide era in Hungary (BENEDEK 1967, 1968a, 1968b, 1969a, 1969b). This situation remained constant later on, in the period between 1971 and 1972 (TANÁCS 1974, 1977) and later on up to present time (TANÁCS & BENEDEK 2004; TANÁCS, BENEDEK & BODNÁR 2008). The main reason for this is the decreasing amount and partial disappearance of Lamiaceae and Fabaceae pollen resources of these kinds of oligoleptic wild bees for broadening use of herbicides at arable land as well as for mechanical weed control becoming a regular practice along road sides and ditches and among cultivated crop fields (BENEDEK 1968a, 1968b, 1997, 1998a, 1998b). Also the decline for more intense agricultural land usage of non cultivated ruderal plots among cultivated crop fields and close-to-nature areas are responsible for the considerable changes in the structures of wild bee species (BENEDEK 1997, 1998a).

Evaluating the structure of lucerne visiting wild bee assemblages from the point of view of climatic demands of species we can conclude that in the five collecting periods the ratio of euryoecious eremophilous species was the highest (between 37.50 % and 48.48 %), which can be explained with the Mediterranean origin of most of these species. The second largest group was made up of hypereuryoecious intermediary species with a ratio between 24.24 % and 34.09 %. This can be explained by the fact that a significant part of these species are Palaearctic or European suggesting their wide ecologic valences. While it meant only the transformation of the species structure until the 1970s without the change in the total density of wild bees (BENEDEK 1997, 1998a, 1998b), by today it resulted in a considerable decline even in the density of wild bees, in addition to structural changes.

The main explanation for changing specific structure and changing densities of wild bees visiting lucerne fields in the past 54 years from the pre-pesticide era until now can be explained as follows. Due to the transforming land usage in Hungary from the pre pesticide era to the mid and late 60s the mosaic pattern of the agricultural land ceased to exist any more. Agricultural technology also changed with the use of high power cultivating machinery, small plots of few hectare area each were united in 2 to 50 or as large as 100 hectares large fields and as a result of monoculture *Medicago sativa* was grown on such large fields too, and so lucerne was abundant in flower ready for lucerne oligoleges to increase their density and dominance within wild bee assemblages. These species, on the other hand, make their nests in the area of lucerne fields so large lucerne crops provided much larger nesting areas to them. Therefore, the density of the *Melitta leporina* (Pz.) and *Rhophitoides canus* Ev., adapted to *Medicago* species as their pollen source, increased significantly from the 50s to the late 60s. The very same changes had adverse effects on other Apoidea species because their nesting areas were destroyed when creating big fields. For the concentrated amount of food at large flowering lucerne fields and the acceptable habitat there the density of some other wild bees, like *Andrena flavipes* Pz., and *Andrena labialis* (K.), remained approximately the same in the 60s and 70s as it was in the pre pesticide era in the 50s.

In recent years a new tendency seems to arise because the dominance of bumble bees (*Bombus* species) has increased rapidly and other groups of wild bee seem to be less numerous than before. This phenomenon, however, needs further studies for a proper explanation.
