Preface.

In completing the work of the 9th Volume of the „Macrolepidoptera of the World", I beg from the reader an indulgent and lenient criticism. The present time, in consequence of European troubles, is the most unsuitable for editing large and costly works, and this 6th volume has had to suffer from still further severe setbacks. The whole volume had been written, the first 800 pages edited, and all the plates prepared, when the war suddenly broke out; only the textual part of the *Lycaenidae* was incomplete. Many well-known authors had promised to undertake the work, but had never carried out their designs. Eventually the author of the greater part of this volume, H. Fruhstorfer, decided to take this chapter in hand. But after the plates had been prepared according to his instructions, he was compelled to make a pause of several years, and death overtook him before he was able to take the work up again.

It was quite impossible to furnish another production of the twenty-two very complicated plates of the *Lycaenidae* according to the proposals of other authors, and it can be easily understood that no collaborator could be found who would conform in every respect to the plates which were already published. Under these circumstances, I, as editor, was obliged to undertake the composition of this chapter myself.

In doing this I thought the correct thing would be to keep strictly to Fruhstorfer's plans, even where my views differed from his. On the one hand, I was forced to do so, by the plates having been executed according to Fruhstorfer's instructions and sketches, and from which the text could not deviate; on the other, I thought thereby to maintain the homogeneous character of the rest of the volume, all of which, excepting the chapter on the *Papilionidae*, is from the pen of Fruhstorfer. By the kind help of Dr. von Rosen of Munich, I was fortunately able to obtain a great deal of information with regard to the copies of the figures; some doubts. however, remained unsolved, since neither the manuscript nor any notes were obtainable from the property left by Fruhstorfer. It seems that he had the intention of inserting new descriptions where he deemed it necessary, and had sketched a few entirely unknown lepidopteral species, with which later authors could do absolutely nothing, as there were no identifications whatsoever.

It took several more years to clear up further doubts, and when all was finished, the edition of the *Lycaenidae* had taken 12 years to complete (from 1915 to 1927) whereas nearly 900 of the Indo-Australian *Rhopalocera* had been accomplished in a few years, and edited in the time suggested in the original programme.

The one hundred and seventy-seven plates of the work have been executed according to the method applied in other countries — nearly all from nature, and I feel infinitely indebted for the helpful assistance I have received in procuring and elaborating the vast number of drawings. It is above all to Lord Rothschild that I owe my gratitude, for having loaned all the *Papilionidae*, written up by Dr. Jordan of the Tring Museum. Moreover, the extensive collection of Semper of the Senckenberg Museum at Frankfort was at my disposal, so that nearly all the illustrations of the Philippine species could be made from the respective authentic specimens. My own collection, which is now also in the Senckenbergianum at Frankfort, and which altogether contained more than 70 000 specimens, had been enlarged to a considerable size by numerous voyages to India, China, and Australia. Fruhstorfer had taken nearly all of plates 51—162 from originals in his collection. and thus an approximate completeness of copies was achieved, in which one or a few forms obtainable to collectors were reproduced. The chief idea in doing this was to limit as much as possible those plates that would have rendered

the cost price of the work too high. Of the gigantic *Zeuxidia* only about 20 per cent. of the known forms were illustrated, but of the small *Lycaenidae* often as much as 60 per cent. of the denominated races appeared, because the former are easily recognized from the descriptions, whereas the subtile distinctions in the small lepidoptera necessitated a greater number of diagrams, and these did not take up too much room.

As the composition of the Hesperids, completed in 1914 after FRUHSTORFER's plans, had remained unprinted until 1927, waiting for the preceding Lycaenids, the question arose whether it should be remodelled and brought up to date by additional annotation, or whether it should be printed in its original form. The reason why I decided to have it printed almost as it stood is that a properly revised version would no longer have corresponded to the plates, which were finished long ago. Also, the increase of material since 1914 did not seem to be great, and if all the forms studied since that year had been appended without omission, the composition of the Hesperids would have been out of all proportion with the other part of the work. Moreover, the time has already come to begin a S u p p l e m e n t a for the whole work, so no appreciable delay is caused by recording these new discoveries in this supplementary volume. Only those larger publications which had come out before 1914 but which could not reach Germany owing to the blockade, such as WATERHOUSE and LYELL, and others, were used in the additional annotations.

The extraordinarily great number of Indo-Australian forms described — the index contains about 14 000 names — made it essential to shorten and condense the treatise as much as possible. On an average, only two or three lines were at our disposal for every form, and thus none of the textual explanations could exceed its scheduled length. Particularly the question whether single forms are entitled to be regarded as species could hardly anywhere be entered into any more than in the other volumes. Such decisions without argument on anatomical circumstances are but of little value, and detailed argument is here quite impracticable owing to the great lack of space. In many cases, the question whether a form is to be considered as a „local race" of its geographically neighbouring form or as a „vicarious species" will to a certain degree be a matter of opinion and cannot therefore be discussed here. We limit ourselves to collecting in paragraphs t h o s e f o r m s w h o s e d i f f e r e n c e s a d m i t o f a g e n e r a l r e v i e w; this rule will, in most cases, naturally assemble the different forms of one species (a so-called „total species") into one group, but this arrangement must not give the impression that all forms jointly dealt with are necessarily specifically related. Such criticisms, then, as this: — that certain forms being jointly quoted are „wrongly placed together", and so on, are to no purpose, excepting in those rare cases where this question is expressly mentioned by the author in the text.

This cursory way of dealing with the forms only made it possible to condense the extraordinarily voluminous material of the Indo-Australian *Rhopalocera* in one volume. In spite of this, the suggested extent of the volume, 1000 pages and 150 plates at the most, was surpassed by 100 pages and 27 plates. It was therefore impossible from the very first to comply with the request of English readers to circumstantiate (and especially to illustrate by drawings) once more in Vol. IX the palearctic forms also penetrating into the Indian region, instead of merely mentioning them by references to Vol. I. I could not bring myself to do this, thus giving the opportunity of acquiring single volumes, to oblige readers who are specialists; the work in its entirety is meant to represent a whole factor, and I do not consider myself entitled, for the sake of single specialists, to make arrangements that would raise the price of the total work by the repetition of the text and illustrations, although this raise, as some subscribers write, would only amount to one or two dozen plates or a few pages of text.

Ever since the work first came out, the question of nomenclature has always aroused the greatest interest in both specialists and laymen. When the work was just beginning, the discussion of the question resulted in a decision by the majority of zoologists to refuse to carry out the „International Rules of Nomenclature" as an o b l i g a t o r y c o d e x. The editor's opinion was, therefore, that owing to the scientific nature of the work, although it is dealing with exclusively entomological material, he should not deviate from the decisive standpoint of general zoology, by forgetting that entomology is only a branch of zoology. At the international congresses I was absolutely unconvinced that the „International Rules" would ever be carried out. Their inadequacy has been proved too clearly to allow any other opinion: not only have they failed to fulfil their principal task — of stabilising the nomenclature — but on the contrary they have increased the confusion by

different misconstructions to the utmost extent. At international congresses it has been suggested, as a way out of the maze, that reliable and comprehensive catalogues, as they come out, be appointed to regulate questions of nomenclature — then voices have been heard demanding courts of arbitration, commissioners to pronounce irrevocable decisions etc. etc. At that time, and still more so today, it was quite impossible to form any idea as to how the questions of nomenclature would find an agreement; today I think it is just as improbable as I did when I finished the earlier volumes that the hitherto existing „Rules of Nomenclature" will ever be universally accepted.

For these reasons I had to leave it to the authors of this work to carry out the rules as far as they wished. Any resistance on the part of the editor to the ideas of the authors with regard to nomenclature would have been useless: it would have spoilt their pleasure in working without leading to an agreement.

The habit favoured nowadays by many people, of noting every insignificant variation from the type, and slight differences in the colour and marking, was exhaustively considered by the authors. The editor thought it best not to interfere with eminent scientific specialists in this respect. The cancellation of any names already given would, in order to avoid its being regarded as an unjust arbitrary action, have caused circumstantial argument, whereby the disposable space would have been by far exceeded. It was therefore decided to leave the matter in the hands of the monographers.

The plates of the 9th volume, like those of the others, and particularly those of the Palearctic section, are not meant to be works of art, for the principal intention of the entire work is that it should be serviceable and cheap. The chromolithographic printing firm of Werner & Winter, where nearly all the plates were produced, has proved in other works (e. g. Saalmüller. „Lepidoptera of Madagascar") that, if few but costly plates are to be offered, it can supply the very best extant illustrations of insects. But to make purchase possible by libraries, universities and high-schools as well as those collectors who could otherwise not afford to buy the „Macrolepidoptera", cheaper methods had to be chosen, so that it was no more possible to bring into exact prominence an insignificant fineness such as of the hair or the scales etc. We had often to renounce the idea of attaining a record in the production of details that were not absolutely necessary for the clearness and utility of the illustrations, so as to be able to increase the number of figures to such an extent as has hitherto not been reached. We also claim a record in the cheapness of the 9th volume, since 5000 coloured illustrations, together with 1100 pages of text have probably never been supplied at a lower price.

Considering this great number of plates, nobody will be disappointed that they are not all of the best quality. The great number of letters addressed to the editor during the long period of composition of the work acknowledge its purpose, and their writers are in general satisfied; we have not aspired higher than this: the „Macrolepidoptera" is a work which is intended to be universally distributed and frequently used, and not one to be glorified as an expensive, splendid book, accessible only to the few.

In choosing specimens to be illustrated, we have preferred those that had not yet been figured in the larger works by Felder, Moore, Semper etc., but those who have not these works at hand can easily find their way about by the aid of the text which points out the various differences.

One great drawback must be mentioned here: the numerous disagreements between the names on the plates and the references to the illustrations in the text. This was chiefly caused by the fact that, after the plates had been completed, the forms here illustrated were detached by the author as new subordinate forms, from the originally annotated ones, under whose names they had been classed. It was then of course impossible to alter the original names of the figures on the plates, as the latter had been produced long before. Some of these differences might perhaps have been avoided if the names on the plates had been replaced by numbers. But in other works where this has been done, it has taken up so much time and given so much work to look up the names according to the numbers, that I thought it was more to the reader's interest to leave things as they stood, although later on several corrections should be necessary in the plates which are provided with exact description.

The insertion of the names in one of the chromo plates occasioned a naturally large number of misprints, since artistic plates cannot be corrected in the same way as set type in letters. We hope that these misprints

caused by this way of explaining the illustrations will be compensated by the much greater handiness of the work produced thereby.

A work that comprises such an immense material must naturally abstain as much as possible from every possible alteration: that is the duty of the critical monograph. Thus the 9th volume considers its chief task lies not in disagreeing on every occasion with older literature, but in appreciating the admirable works of former specialists, which are the foundations of this work.

The present 9th volume completes the second major division of the entire work, inasmuch as all the butterflies known on the earth have been dealt with. On 549 plates more than 20 000 figures of butterflies have been reproduced, and as the whole text enumerates about 30 000 denominated forms of the butterflies of the entire fauna, there is on an average one figure to every second form, so that at least those species which are in the possession of the private collector are nearly all represented.

Beside the numbers of *Rhopalocera*, 400 plates of *Heterocera* have been produced, so that, when the exotic *Saturnidae* and *Sphingidae* have been completely written up, all the larger moths will have been classified except the few genera of the *Cossidae* and *Noctuidae* — so the final manufacture of all the material is soon to be expected. In any case, a considerable part of the pause of nearly ten years, caused by war and revolution, and during which the work made but slow progress, can be made up. The noticeable recovery and strengthening brought about by my recent stay in Central Brazil will, I trust, make itself apparent, after my return to Europe, in the speedy completion of the work.

For the present, I beg to express my sincere thanks to all who have aided me in the accomplishment of my great task: particularly to Prof. Dr. Draudt of Darmstadt, who was kind enough to relieve me of the troublesome business of organization and editorial work during my present journey of convalescence.

Finally I must mention that the editor's responsibility refers only to the German text. Of the French edition which has entirely passed into the hands of the firm of Le Moult, I have no knowledge whatsoever.

Araraquara, March 24th 1927.

II. SECTION:

The Macrolepidoptera of the Exotic Fauna

IX. VOLUME:

THE RHOPALOCERA

OF THE

INDO-AUSTRALIAN FAUNAL REGION

Introduction.

Scientific zoologists as well as collectors who do not know East India from personal experience mostly connect with the name of this country the idea of an immense abundance of forms. In the picture which the layman draws for himself of an Indian landscape a luxurious growth of vegetation usually covers every spot of the ground, and lepidopterists who only know South Asia from the collections of dealers in "centuries", so rich in individuals, are easily misled into the belief that any locality of India harbours an inexhaustible multitude of still undiscovered treasures for the collector, that every energetic collecting expedition must bring an abundance of new discoveries and unprofitable day's excursions be an impossibility there.

But this is only very partially the case. Even the most popular tour through India, from Ceylon via Tuticorin to Madras — Bombay — Calcutta — Darjiling is enough to prove that East India is only here and there the luxurious dream-land which hovers before you when confined to our poor European soil, like a lost Paradise at an unattainable distance. For hours and days the way leads through regions which, planted in the most uniform manner with young cotton-plants and stripped of their primitive vegetation, resemble enormous potato-fields of the size of small kingdoms. Sometimes also on the Indian tableland the track goes through dry regions almost bare of plants, in crossing which you think yourself transplanted to the African deserts. The transition from these wastes into a magnificent valley, often a very Paradise of beauty, is at times quite unprepared for, and the suddenness of the change may tend to heighten the overwhelming impression which this new landscape makes upon you.

As locally so seasonally also we meet sometimes with sharp contrasts. A South Indian landscape which we saw for the first time in the rainy season, when everything was green and flourishing, we should not recognise in the dry season. Thick white or red dust covers the leathery, yellowed leaves of the once fresh and attractive shrubs and trees. The beds of the rivers and brooks lie dry and the hot, quivering atmosphere hangs leaden over the dead landscape. Only when the sun has set a part of the scanty animal world awakes to shy nocturnal life, to take refuge again in or on the ground as soon as the day-star rises in the cloudless blue sky.

So also from the lepidopterist's point of view India may be described as the land of contrasts. Locally we know of places where the fauna is exceedingly varied and rich in forms, and also of some where, at least during the greater part of the year, the butterfly world falls considerably behind the better European districts. Insignificant, pale-coloured, diminutive forms constitute the larger number of those which we meet with, as poor in beauty and colour as the joyless scenery which surrounds them. And so also the fauna of one and the same place is contrasted according to the time of year. India is the land of seasonal dimorphism, which occurs in a very large number of Lepidoptera in such a striking manner as is not found in any other region of the earth, with the exception of a few African districts. The wet-season forms are mostly larger, brighter, more deeply coloured, and often also more abundant than the corresponding dry-season forms. Also the dry-season forms mostly develop much more slowly than those of the wet-season, so that where the two seasons of the year are of equal length the wet-season produces more generations than the dry.

It has already been said in the general introduction in the first volume that the Indo-Australian fauna is composed of two very different faunistic types, which however have been completely blended. The first type of fauna is the specifically Indian, which extends over all India with the whole of the Malayan islands. It sends single offshoots into the Palaearctic Region, has its principal centre on the southern slopes of the Himalayas and in the Malayan islands, and coming from the north has spread far over Australia, forcibly driving the scanty Australian fauna, which forms the second type, towards the south. There remained then to this second type only the south and west of the Australian continent, Tasmania and (harbouring a last faunistic remnant) New Zealand. There in the extreme south, which is

rendered unsuitable for the Indian immigrants by the long, cold, and sometimes rainy winter, the type of the older Australian lepidopterous fauna is still preserved. The Australian *Synemon*, *Hepialus* and *Xyleutes*, *Charagia*, *Oxycanus*, *Pielus* and the remarkable *Zelotypia stacyi* are such original inhabitants of the land; primitive Bombycids, Microlepidoptera, and of the butterflies Satyrids of the genera *Heteronympha*, *Hypocysta* and *Xenica*.

It is not only the seasonal changes that make the Indian Lepidoptera dimorphic. Just the part of the Indo-Australian Region that is best adapted for the development of a rich lepidopterous fauna, namely the region of the equatorial forests, is broken up into numerous large and small islands and peninsulas by the formation of the Malay Sea. According to its position with regard to the trade-winds, in, at or beyond the limit of regular winds, almost every one of the Malayan islands has developed a character of its own, which can sometimes be sharply distinguished in islands lying close together. We find then that on almost every island or group of islands the Lepidoptera of the Indo-Australian Region have developed special forms diverging in a definite direction. These characteristics may be very slight and so little noticeable that the older authors never mentioned them at all; but they may also be so obvious as to be immediately noticed by everyone who works in one of these specialised districts. It was already mentioned by A. H. Wallace that most of the Lepidoptera from certain districts of Celebes have a similarly curved costal margin of the wings, differing from that of nearly allied species found elsewhere, and L. Kuhlmann, who compared the butterflies of Ceram with those of other islands, established the fact that of all the local forms of a species the largest almost always occurs on Ceram.

As a third cause which favourably influences the development of polymorphism, we have specially mentioned Mimicry in the general introduction. As almost every one of the often widely separated islands has a different model, the mimic was compelled to choose a different garb in the various districts. For instance, *Papilio polytes*, which mimics an Aristolochia-Papilio, occurs everywhere from East China to the extreme west of East India. But there is no Aristolochia-Papilio of like distribution; in the Himalayas occurs *P. aristolochiae*, on Ceylon *hector* and *ceylanicus*, on Borneo *antiphus*, etc. Consequently the mimetic ♀ of *P. polytes* could only wear its *polytes*-garb, copied from *P. aristolochiae*, in the localities of the latter, and was obliged on Ceylon as *romulus* to wear the *hector*-garb, on Borneo as *melanides* the *antiphus*-garb, etc. There is no more conclusive evidence for proving that mimetic imitation is intentional than an exact examination and geographical comparison of the various lepidopterous forms of the Indo-Australian fauna.

It is in the Malay Archipelago that the Indian Region produces the greatest variety of tropical lepidopterous forms. From there the number of Lepidoptera decreases most rapidly towards the South. The interior Australian desert was impassable for most of the Indian immigrants. Only the narrow strip of forest along the east coast of Australia offered to a limited number of the larger butterflies a way to advance further south. But on the whole the south of Australia is especially poor in butterflies, and in my wanderings over the profuse carpet of vegetation which one finds in New South Wales, so rich in flowers but almost completely without animal life, it often seemed to me inexplicable that a vegetation so rich and everywhere so favourable to butterfly life, could be so strangely devoid of it, and even in glorious summer weather live and die untasted.

Towards the East the ocean has permitted no wide distribution of the Malayan lepidopterous world. More and more dispersed, more irregular and smaller become the groups of islands, always more furious the seething of the sea at high tide, and always more powerful the storms which lash the coasts of the islands. It is precisely these sweeping hurricanes which check the distribution of the delicate-winged Lepidoptera and endanger their existence. In my work on the Lepidoptera of the Marshall Islands I have expressed the conjecture that the lepidopterous fauna of these remote islands is sometimes partly or almost entirely annihilated and has to be formed anew by accidental immigrants. Thus it happens that in some parts of the extreme east of the Indian Region there exists no fixed fauna, i. e. composed year in, year out of the same species of Lepidoptera, i. e. that a collector 40 years ago must have met with a different set of species on certain remote islands from what he would find to-day in the same localities.

Towards the West the southern limit of the region is in the Indian Ocean. The meagre fauna of the Laccadive Islands and the still more insignificant one of the Maldives consist only of scanty forms immigrated from India; the Seychelles and Maskarenes have along with many specific forms which however are all allied to the Ethiopian type, a thoroughly African fauna, so that the broad strip of sea lying between the 60. and 70. degrees of longitude is to be regarded as the faunistic boundary. In its northern part the Indian Region touches in South Arabia on the Ethiopian, in North-West India on the Palaearctic Region. Where the exact boundary lies in Inner Arabia, which has been as yet but little explored as regards Lepidoptera, we cannot at present determine. Maskat is entirely Indian, Aden thoroughly African in its lepidopterous fauna. Between these two districts extend deserts, which stretch from Nejd far towards the South-East, and reach the sea in the strip of coast, outwardly rocky and inwardly sandy, between Makalla and Mirbad. In this border-land there are probably only very few Lepidoptera, principally Noctuids of the genera *Anomis*, *Eurrhipia*, *Ophiusa*, and some butterflies common to both faunas, such as *Junonia oenone*, *Hypolimnas misippus*, *Lycaena baetica* and a few others.

The boundary of the Indo-Australian Region towards the North-West and North is more difficult to fix. The most southerly part of Persia, Beluchistan and the Punjab are still Indian, but form the borderlands, which join the districts of Kangra and Kulu in Southern Kashmir. But in Kashmir itself only the southern slopes of the Himalayas are still Indian; at the higher altitudes, and especially the localities which are more open towards the North, where the summer does not bring the terrible heat which in the neighbourhood of Lahore has turned the ground into a desert, Palaearctic forms occur in such numbers that the fauna is only connected with that of the adjoining district by a slight intermixture of Indian forms.

Eastwards of this great northerly sweep in the neighbourhood of Kashmir, the Indo-Palaearctic boundary line suddenly recedes southwards. No Indian fauna can endure the ice-cold snowy winters of Tibet. Anything that can enjoy the sultry valleys of the Lower Indus and Ganges must succomb to the cutting wind of high-lying Tibet. Not till we approach Nepal, Sikkim and Bhutan do we get the double chains of protecting mountain ridges which give to the southernmost part of Tibet the character of a faunistic boundary-land. Then in the east of Tibet, where a still unexplored district crossed by mighty chains of mountains stretching north and south forms the watershed between the Mekong and Yang-tse-kiang Rivers, the natural boundary of the two faunistic regions may be placed. Then it follows the changeable Yang-tse Valley. Only where this gigantic river takes a wide sweep in southern Se-chuen towards Yun-nan, the boundary runs north of it, in the south of Ta-tsien-lu; then it follows, through the Chinese plain, the 30. degree of N. latitude.

I have given considerable attention to the fixing of the Indo-Palaearctic boundary, which I have already set forth in detail in the introduction to the Palaearctic part. It is not a list of uncritically registered species of a district, or even the entirely valueless placing together of genera which depend on individual opinions, not being fixed entities, that gives us a definite clue as to the fauna to which a district belongs, but only the survey for faunistic purposes by trained eyes, preferably by personal observation. The casual appearance of a *Melanitis leda* does not prove that we are on Indo-Australian ground, but where it occurs commonly as a characteristic buttertly of the district, we can appeal to it as evidence that we are in the Indian faunistic Region.

By personal observation I was able to convince myself that the question as to which faunistic region a place belongs to is by no means specially difficult to settle. In Shanghai the 10 commonest butterflies, arranged according to the frequency of their occurrence, are the respective local forms of the following species:

Pieris napi, Colias hyale, Gonepteryx rhamni, Pyrameis cardui, Chrysophanus phlaeas, Papilio xuthus, Sericinus telamon, Lycaena baetica, Pieris melete, Parnara guttata.

On Hong-Kong, lying only 10 degrees further south, not a single one of these species is specially common at any time of the year, *Lycaena baetica* and *Pyrameis cardui* alone being found there. The 10 commonest Rhopalocera, likewise arranged according to their abundance (say about October), are the following:

Terias hecabe, Danais vulgaris, Euploea superba, Melanitis leda, Pieris canidia, Messaras erymanthis, Neptis eurynome, Mycalesis perseus, Catopsilia pomona, Hebomoia glaucippe.

A large proportion of these species we have made acquaintance with in the 1. part of our work as observed in the Palaearctic Region, but never as characteristic butterflies; every one of these 10 species is characteristic of their native places by their numerous, sometimes abundant occurrence. But only the commonest Lepidoptera of a district are of any use in settling disputed questions of zoogeography; as rarities they have, because exceptional appearances, sometimes only quite subordinate value, sometimes none at all.

As also on the southern Japanese island the commonest butterflies are *Lycaena argiolus, Chrysophanus phlaeas, Pieris napi, Ypthima argus, Pieris melete, Papilio machaon,* etc., etc., this island is still absolutely and thoroughly Palaearctic, however many otherwise Indian *Papilio* may appear there as transient summer visitors; and in like manner the Liu Kiu island Okinawa with its *Hestia, Danais, Hebomoia, Hypolimnas,* etc., is thoroughly Indo-Australian. Thus the 30. degree of latitude divides the islands of the two faunistic regions in the Chinese Sea.

In characterising the habitus of a fauna one has to consider the abundance in individuals much less than in the case of adducing geographical statistic differences. One gets a good idea of the habitus not only by observing the fauna in its native country, but also in examining a collection from there as complete as possible. It is the totality of the variations in form, colouring and pattern that admits of a survey and makes us acquainted with the most conspicuous peculiarities. We have already pointed out in the introduction to the American part of our work that in the Indian Region the gorgeous colouring of shining bands or spots, mostly yellow or metallic blue, on a deep black ground-colour, is far less common than in tropical America. The magnificent blue of *Morpho, Prepona, Myscelia, Callicore,* of many large *Thecla,* etc., occurs very rarely in the Indian Region; but the ochrous colours, which sometimes predominate in India through whole extensive genera (*Cynthia, Cirrhochroa, Messaras, Charaxes, Clerome,* etc., etc.,) are strongly developed. The hyaline species, so abundant in tropical America, such as the Ithomiids, *Haetera,*

the *Zeonia*, etc., are completely wanting. On the contrary the Indies are much richer in grotesque and exaggerated forms, which cause well-founded astonishment even to the layman, e. g. *Leptocircus*, *Butanitis*, *Himantopterus*, *Cyrestis*, etc.

As regards the various pecularities of the character of the different groups of Lepidoptera represented in the Indo-Australian Region we refer to the parts of this work dealing with them, and we only touch here on a few specially striking peculiarities of the families, or those specially characteristic of the region.

The **Papilionids** from the South-East of the Old World are widely known by a group which formerly enjoyed a very special attention from the amateur and collector as a single genus under the name of *Ornithoptera*. Equally noteworthy for their size and the gorgeousness of their colouring, they belong undoubtedly to the most imposing of the known forms of the animal world. However little satisfactory the biological explanations hitherto attempted may have been, it is clear that in the *Ornithoptera* we have before us developments of nature in which the attainment of a certain conspicuous beauty has undoubtedly been the aim of their creation; this aim may be the expression of the mood of a creator, or the final outcome of a series of biological necessities governed by selection. The males of the various *Ornithoptera* forms contrast with their unicolorous females by their brilliant colouring, sometimes of red-gold, sometimes of green, blue or yellow, and their agreement is so much the more remarkable in that morphologically the *Ornithoptera* do not form an exclusive group and the genus can scarcely be maintained on a strictly systematic basis. They are doubtless congeneric with the Aristolochia-Papilios, which are widely distributed in India, and closely allied groups are found among the Papilionids of the New World. — The Parnassiids scarcely show any independent forms in the Indian Region; on the contrary the representatives of the Apollo-Butterflies in the north of the region are all local forms of otherwise Palaearctic species. — We find another singular modification of the Papilionids in the specifically Indian *Leptocircus*, long-tailed, vitreous-winged little insects of Hesperid-like habitus, which boom about from flower to flower with buzzing flight, alternately raising and lowering the ribbon-like appendages of their wings.

The **Pierids** are chiefly remarkable for the gay-coloured under surfaces of very many species, which attain their highest development in *Delias* and here often show an altogether ideally beautiful arrangement of intensively coloured bands and spots, more gorgeous than are found either in America or in Africa or Europe, although a gay-coloured under surface occurs occasionally in certain Pierids of the New World *(Perhybris, Dismorphia, Archonias)* as a product of mimicry.

In the **Danaids** the development of the gigantic *Hestia* in the Indian Region is worthy of mention. The pattern and colouring of the Hestias is striking and unusual, but still more so is the flight, which causes everyone passing through the Indian woods to stop and wonder how it is possible to the insect with the wings apparently stationary and half erect to be carried first to one side, then to the other. The *Danais* themselves show an immense number of individuals in India, rivalling the *Euploea*, crowds of which sometimes cover the flowering trees like thick clouds or fly over the country in long-continued swarms.

In contrast with this abundance, the **Satyrids** are decidedly less prominent in the Indo-Australian Region. Especially in the tropical part of the region the true Satyrids are confined to small, unicolorous, dark forms, and only the subgroup *Elymniinae* develops, mainly by mimicry, a gay-coloured dress, borrowed from brilliant *Danais* and iridescent *Euploea*. In the north the Indian Region still partakes somewhat of the stateliness of the neighbouring Palaearctic Satyrids, and in South Australia the family again develops varied series of forms, which however are not comparable to those of analogous districts in the Northern Hemisphere.

The **Morphids** of the Indian Region neither form a homogenous group among themselves nor stand in direct relation to the American genus *Morpho*, on which the family name was founded. Analogies are found rather between them and the Neotropical *Brassolidae*. Viewed as a whole we find in the Morphids both of the Old and the New World modifications of the Satyrid characteristics, which harmonise with one another in similarities which are sometimes ancestral, sometimes due to convergence. Such characters are their nocturnal flight, the feeding of the larvae on Monocotyledons, and many others.

The **Nymphalids** occur in the Indo-Australian Region, as in all the others, uniformly, certainly and universally. As the Nymphalids, represented by certain forms of *Argynnis*, struggle in Greenland, Alaska and Nova Sembla against the inhospitality of nature, so we find *Pyrameis*, *Junonia* and *Hypolimnas* even wandering over the southern ice-sea and on the most advanced outposts in the open ocean, where the family sometimes still develops powerful, characteristic forms, such as *Pyrameis gonerilla* and *tammeamea*.

The **Erycinids** are but scantily represented in the large Indo-Australian Region. As small copies of the Nymphalids we meet with them almost everywhere, but nowhere in large numbers and without being able in any one place to develop such numerous forms as in the American Region.

The **Lycaenids** attain in the genus *Arhopala* a considerable size and have often a wonderful, shining blue gloss. But the smallest known species also occurs in the Indo-Australian Region, the

diminutive *Zizera,* the smallest forms of which can only be seen by stooping down and carefully examining the tufts of grass, and which in danger crawl away and hide between the blades like little midges. We also find among the Indo-Australian Lycaenids many biologically interesting species, which sometimes live for a time with ants, and even occasionally in the larval stage appear to feed on the early stages of the ants.

The Indian **Hesperids** occur in much less numerous forms than the American ones, but include many particularly large species. Several genera, as *Ismene, Rhopalocampta, Hasora,* etc., are partly nocturnal in their habits and remain concealed during the day.

As transitions from the large division of the Butterflies, especially from the *Grypocera* to the *Heterocera,* we may regard the Old World **Synemon,** just as the American Castniids. They form one genus confined to Australia and their especially numerous occurrence in its western and south-western parts proves that in them we are dealing with an old genus, driven to this remote corner of the earth by the immigrant Indian fauna of the North. Their close connection with the tropical Indian *Neocastnia* and the genuine New World *Castnia* would be difficult to prove.

The **Zygaenidae** are represented in the Indo-Australian Region especially by the group of the Chalcosiids and offer as such all imaginable grades of mimetic colouring. They have even borrowed the habits of their models and copy sometimes protected Butterflies, sometimes Syntomids or even other insects, not belonging to the Lepidoptera. Certain parallels with American moths are very note-worthy. Thus the moths of the genus *Amesia* in danger seek their safety at first in flight, but feign death when touched, lying perfectly still with the wings folded together behind. At the same time, with a hissing or chirping noise, they exude from the thorax shiny drops of froth, which gradually cover the whole insect with yellow spittle, just as do the members of the American genus *Anthomyza.* The Indian *Himantopterus,* like their African relatives, are believed to be associated with the Termites.

Apparently connected with some groups of the Zygaenid family are the **Epicopeia,** a nocturnal genus, mimetically altered to such an extent that it is impossible now to conjecture what habitus the insects possessed before their mimetic transformation. Perhaps they are descended from *Histia*-like Chalcosiids, perhaps it is more correct with Hampson to place them among the *Uraniidae.*

The **Syntomidae** all belong to proportionately few genera and cannot be compared in their variability and their mimetic disguises with the American members of this family. Although here and there brilliant metallic colours are developed in India, yet the larger number of the Old World Syntomids copy black-yellow wasps and their costume appears therefore from the biological standpoint more practical than brilliant as is that of the American Glaucopids, which veritably resemble flying precious stones and suggest a comparison with the American Humming-birds, just as a parallel has been drawn between the group of *Ornithoptera* and the New Guinea birds of Paradise.

From them the very remarkable Papuan **Cocytia** lead us to the **Lithosiids** and the true **Arctiidae.** The centre of development of this family lies in the Temperate Zone in as much as just the largest and most brilliant species do not live between the tropics. The *Lithosiids* and the *Nolids* are generally regarded as old, primitive groups, a few parallel branches of which have further advanced in evolution and become the ancestors of the more highly developed groups of Heterocera of modern times. Very noticeable is the constancy in size, habitus, and sometimes also colouring, which connects the Lithosiids of the most different countries together and in many cases even extends to the habits.

The **Liparids** attain their highest development in the Indo-Australian Region. As in the extreme north of the Arctic district, we find them also far in the south in on the whole similar development: and as they do not produce gigantic forms, so also as regards colouring and markings they are mostly confined to the same regular pattern: a light, often satiny yellow or white with dark central lunule and blackish serrated lines on the forewing. Even as regards their biological conditions they show a great uniformity. We see exactly the same circling flight in the South-East Asiatic *Pantara* as in the European *Orgyia,* and a female of *Epicoma melanosticta* beaten out in the Australian bush assumes exactly the same peculiat position, with rolled-up abdomen and wings erected, as a female of *Psilura monacha* taken in a North German pine forest.

The **Limacodids** play a prominent part in the Indo-Australian Region. The largest known forms of the family are found in the Indian *Scopelodes* and *Phocoderma,* and in Australia the occurrence of many Limacodid larvae on the indigenous Eucalyptus indicates a long and very close adaptation to this part of the world. The powerful urticating organs of the larva probably attain their highest development in the Australian *Doratifera vulnerans,* yet the larva of the Chinese *Parasa sinensis* can sting almost as strongly.

The **Psychids,** on account of a certain uniformity in their distribution, take a less prominent place in the Indo-Australian Region compared with the other Heterocera, although the largest known form of the family is found in the Australian *Metura elongata.* But while in the Indian Region they surpass those

of the American in number of species, in number of individuals they remain far behind their representatives in the New World, where certain species, e. g. *Oiketicus platensis,* have become regular enemies to horticulture.

The **Lasiocampids,** on the whole of pretty similar distribution over all non-polar lands, show remarkable peculiarities in many districts of the Indo-Australian Region. In the first place, certain sections of this family form a part of that typical Australian primitive fauna which, confined to the south of the continent, has there produced forms to which we find no parallel elsewhere. Everyone who has collected in Australia will remember the gigantic Zebra larvae, which produce *Chalepteryx collesi,* formerly included among the Saturniids; also the sharp-snouted *Opsirhina* and others. As in the Palaearctic Region the pine moth, *Dendrolimus pini,* sometimes increases to such an extent as to become a menace to the forests, so also in India we meet with many Lasiocampids among the commonest moths; thus in India and South China *Trabala vishnu,* whose bright-coloured larvae with pencil-bearing striped heads may be found on almost every bush and all the year round. *Suana concolor* is distinguished by powerfully developed females, which stand in much the same proportion to their only medium-sized males as the Liparid *Ocneria dispar.*

The **Saturniids** attain in the Indian *Attacus atlas* the largest wing area known in the Lepidoptera, although they are surpassed in expanse by some *Papilio* females and by the American Noctuid *Thysania agrippina.* On the whole the Indo-Australian Region has not so many Saturniids as America, but it possesses some very singular forms in the long-tailed *Coscinocera.*

The **Bombycidae** and **Eupterotidae** are families with very few forms, which come between the Saturniids and Lasiocampids. The former must be specially mentioned on account of the silkworm, *Bombyx mori,* an insect of enormous commercial and economic importance. As we have already noticed in the general introduction (vol. I), it may now be accepted with certainty that the silkworm comes originally from China, but whether from the Palaearctic North or the Indo-Australian South cannot now be determined on account of its general naturalisation and importation.

The **Sphingids** are represented in the Indo-Australian Region by very many species, but their larvae show less tendency towards those grotesque forms such as America possesses in the zebra-like *Pseudosphinx* and in the log-like *Philampelus anchemolus* and *Pachylia* larvae, under the weight of which large branches on the bushes are bent down to the ground. The largest Indo-Australian Sphingids have simple green *Smerinthus* larvae; they are *Langia zenzeroides* (which also encroaches on the Palaearctic Region), the expanse of which insect is 17 cm and whose larva might be taken for an enormous *Amorpha populi* larva whose lateral stripes are lost, as well as the still larger *Coequosa* and *Metamimas,* which belong to the old Southern Australian fauna. Their larvae, though green in colour and with the well-known oblique lateral streaks, are in form perhaps the most singular of all known Sphingid larvae. Whilst the horn on the tail is wanting, the head is produced into a long, somewhat curved point, so that it forms a true continuation of the anteriorly much diminished body. If we imagine the larva in its resting posture, namely very much erected, it forms a single long green horn. — Besides this the Indo-Australian Sphingid larvae often resemble snakes' heads, their two lateral eye-spots, by the extremely vivid glitter of the enamel-gloss on them, not only imitating the eye, but also the gleam of the snake; an appearance to which I have found no parallel in Palaearctic lands.

The **Notodontids** can scarcely be discussed as a whole on account of their heterogeneity, already mentioned in the introduction to the American part. It may be particularly mentioned that many specifically peculiar forms, such as *Cerura,* are found in the remotest parts of Australia. Many groups of which the Palaearctic fauna only possesses small, inconspicuous forms attain in the Indo-Australian fauna to a notable size.

The **Noctuids** of the Indo-Australian Region bear the same relation to those of the Palaearctic lands as those of South America to the North American fauna. In place of *Catocala* occurs *Ophideres,* in place of *Mania* and *Spinther ops* the bat-like *Patula* and *Nyctipao.* Singular modifications of the hindwing of the male are often found in the giant Noctuids of the Indo-Australian Region, and are perhaps connected with the peculiar rattling or cracking sounds which the males make in flying, and which reminded me forcibly of the rattling of the Neotropical *Ageronia.* Taken as a whole the Noctuids do not form in the Indo-Australian Region such an overwhelmingly large proportion of the Lepidoptera as was the case in the Palaearctic Region.

Finally, the Indo-Australian **Geometrids** are confined to similar limits in this as in the Palaearctic and American Regions. Species of *Elphos* and *Erebomorpha* are here, as in the Palaearctic Region, the largest Geometers. Their slenderness forms a noteworthy contrast to the heavy, stout-bodied *Oenochroma,* which are among the more remarkable of the Australian forms. It was erroneously believed for a long time that a gigantic Geometer had been found in *Nyctalemon,* but the larva is 16-legged, and its proper place is beside *Urania.*

To give further particulars about the enormous number of genera and species of the Indo-Australian Region is beyond the scope of this introduction. But even of the special part which follows, we must say that it is only a trifling fragment; only a preliminary study, serviceable for pointing out the place where the crowds of annually discovered species are to be arranged. The very districts of our region most rich in species — North-East India and the interior of the Malayan lands — have scarcely yet been geographically explored; and if in the beginning of this chapter we warned against the idea that every imaginable district of East India offers a quarry for daily new discoveries in the lepidopterological sphere, yet there are still enough islands and mountain regions which in this respect surpass the most daring hopes. The extreme south of China, the numerous tracts of mountains into which the eastern Himalayas are broken up, the interior of the larger, as yet little cultivated islands, such as Ceram, Borneo and New Guinea, must still offer much which awaits discovery; the most gorgeous giant butterflies of this region, among them the enormous Ornithoptera *Papilio alexandrae*, were not made known until quite recently.

DIURNA

OR

BUTTERFLIES

1. Family: **Papilionidae, Swallowtails.**

Proboscis always well developed. Palpi small and appressed to the head, rarely large and projecting (*Teinopalpus*). Three types of antennae occur: the fine sensory hairs beneath and laterally are almost equally distributed over the proximal part of each segment, or there is a cavity on each side which is covered with sensory hairs (recalling the Nymphalids), or there is only one row of such cavities present (recalling the Pierids); the upperside either scaled or naked. Mesothorax very powerful, the sternum completely fused with the episternum, the suture outwardly quite wanting as in the Pierids, which distinguishes these two families from all other Lepidoptera. Foreleg fully developed; foretibia with spur on the underside. Claws simple, very rarely cleft as in the Pierids (in one species of *Leptocircus*); paronychium and pulvillus wanting. The cell in both wings closed; in the forewing the 2. discocellular the longest (between the 1. and 2. radial), the 2. radial branching off from the lower angle of the cell, because the 3. transverse vein stands in or almost in the prolongation of the median, and therefore 4 veins arise from the hinderside of the cell (which misled the older authors into speaking of 4 median veins; all Lepidoptera however have only 2 median branches), the upper inner marginal vein (= 1. submedian) wanting, but its proximal part often present as a short transverse vein arising from the median near the base, which is mostly curved outwards at the tip, the 3. submedian vein running free into the hindmargin; hindwing with precostal vein and one submedian vein. — Egg round or flattened, without prominent sculpturing. — Larva before the first moult with rows of bristle-bearing tubercles, which in the later stages disappear, or are replaced by fleshy processes or hard spines; on the neck a reversible fleshy fork of a yellow or red colour, which secretes an odour and is stretched out in defence (the osmaterium); lives free, but some Papilios by bending over the edges of leaves make a sort of tunnel in which the larva conceals itself; many forms hide during the day, many also are gregarious. — Pupa fastened at the end of the abdomen and by a girth encircling the thorax and wing-cases, with the head upwards (older authors, and Rippon even quite recently, erroneously represent the pupa as having the head downwards; the error arose from the fact that the heavy larvae of the Aristolochia Papilios, for instance, fasten themselves on hanging leaves with the head towards the base of the leaf); in other forms (e. g. *Parnassius*) the pupa in a loose cocoon on the earth or just under its surface; three movable abdominal segments.

This cosmopolitan family occurs principally in the tropics, and only a few forms cross the polar circle; yet the northern temperate zone possesses in *Parnassius* a type which is wanting in the true tropics.

1. Genus: **Papilio L.**, *Swallowtails.*

Forewing always with median spur (= 1. submedian); at least one of the discocellulars placed longitudinally; hindwing with precostal cell. All the species have the pupa fastened by a girth. — The so-called genus *Papilio* is divided into three large divisions which are sharply separated from one another in the larva, pupa and imago. This natural classification was discovered by Horsfield as long ago as 1856, but not recognised by later authors (Erich Haase excepted). We begin with the Aristolochia Papilios. These strong smelling forms, so tenacious of life, are frequently mimicked by species of the other two groups, as well as by forms of other families, and even until quite recently models and mimics have often been regarded as closely allied.

A. **Aristolochia Papilios.**

Antenna without scales, except dorsally at the base, beneath on both sides with a sharply defined sensory cavity on each segment. The outer ventral row of spines of the tarsi not separated from the dorsal spines by a spineless longitudinal depression. — Larva on Aristolochia, rarely on allied plants; densely covered with very short hairs, which give the larva a velvety appearance; only the head, the prothoracic sclerite and the legs shiny; each segment with a belt of fleshy tubercles or processes which bear hairs, but no strong spines; the tubercles of the prothorax sometimes prolonged (in a number of American forms). — Pupa dorsally strongly incurved before the middle and posteriorly arched; wing-cases strongly projecting; the head truncate,

with distinct horns; on the abdomen dorsally a row of humps or lobes on each side. — Tropical insects; one species distributed northwards to Japan; 2 species in North America; not represented in Europe, Central Asia or Africa, on the other hand one very peculiar species in Madagascar. The African *Papilio zalmoxis* and *antimachus*, placed here by some authors on account of their size, belong to the second division, the Fluted Papilios.

In older works and in most collections we find a number of Aristolochia Papilios grouped together under the name of *Ornithoptera*. The term embraces the *priamus*, *brookiana* and *pompeus* groups, but is scientifically untenable, because not definable morphologically. Apart from the fact that the name *Troides* is older, all the *Ornithoptera* are true *Papilio*, as is proved even by the larva, which does not differ from the larvae of other Aristolochia Papilios in anything except perhaps its somewhat larger size. Apart from the size the characterisation of the group is only founded upon purely external peculiarities of form and colouring, some of which have broken down in the light of more recent discoveries. We therefore only mention the name *Ornithoptera* here on account of its having been adopted in older works and collections. With the single exception of *P. aeacus*, which is treated in vol. I (pl. 1), the whole of the Papilios which belong here are confined to the Indo-Australian Region.

The Aristolochia Papilios of the Oriental Region are essentially insects of the forests and thickets; they principally fly in open spaces in the woods and at their edges and are often taken on flowering trees and shrubs. They usually flutter slowly through the air, though often high above the ground; but the larger species are adroit and powerful fliers. To this division belong the most beautiful of all Lepidoptera; New Guinea especially is rich in large forms with glittering green and gold ♂♂. The ♀ of *P. alexandrae* with the forewing 135 mm. long is the largest of all known butterflies, if not the largest of all Lepidoptera.

P. victoriae is confined to the Solomon Islands, where this magnificent butterfly appears to occur on all the larger islands. The 3. subcostal of the forewing arises from the upper angle of the cell or distally to it, more rarely somewhat before the angle. Head and thorax entirely black; abdomen grey-yellow, stigma-spots and in the ♂ a row of subdorsal dots, as well as the base, black. Forewing of the ♂ narrow, with scent-patch; cell very broad; a large basal area as well as a subapical area golden green; hindwing green, distally more or less golden, all round the margin and often also a part of the disc black. ♀ variable in size and markings; black-brown with yellowish white or white spots; forewing with a large basal spot in the cell and a second spot in the middle of it, these spots often confluent; 2 rows of spots between cell and distal margin; hindwing with large costal area and 2 rows of spots between cell and distal margin. Larva black, the tubercles entirely red. Pupa on the upperside yellow between the only moderately projecting wing-cases. The butterfly is not rare on some of the islands; but the ♂♂ are only taken in small numbers, as they fly quickly and high

regis. and mostly remain in the tops of trees. The insect is not yet known from San Christoval. — **regis** *Rothsch.* is the most northerly form, discovered by Ribbe on Bougainville, where A. S. Meek afterwards captured a good series. The golden green subapical area of the ♂ long, especially the first spot longer than in the other subspecies; usually the area consists of only 2 spots, yet frequently a third is also developed and sometimes a fourth indicated. The spots of the ♀ are very variable, as in the other subspecies, but the submarginal spots

isabellae. in *regis* are very small. — **isabellae** *Rothsch.* occurs on Ysabel and probably also on Choiseul. Connects *regis* with *victoriae*. The golden green subapical area of the forewing of the ♂ is longer and narrower than in *victoriae*, and shorter and broader than in *regis*. ♀ similar to that of *regis*, but the submarginal spots

victoriae. larger. — **victoriae** *Gray* (6 a) we know from the islands of Guadalcanar, Tulagi and Florida. The subapical area of the forewing of the ♂ consists of 3 spots and is about as long as broad; sometimes the third spot is very small, whilst in the only ♂ from Tulagi known to me a small fourth spot is present; many specimens bear on the hindwing black spots between the cell and the yellow submarginal spots. In the ♀ the fifth submarginal spot

reginae. of the forewing is very small, sometimes entirely absent. — **reginae** *Salv.* inhabits Maleita. The subapical area of the forewing of the ♂ consists of 4 spots, of which the last is small; the third spot is larger than in the other subspecies; the hindwing is velvety black between the cell and the submarginal spots, as is also the hindmarginal area. In the ♀ the discal and submarginal spots of both wings are large, and both the proximal

rubianus. spots of the forewing and the discal spots of the hindwing are more or less strongly yellow. — **rubianus** *Rothsch.* (6 b), from Rubiana and Kulambangra, is noticeable in the ♂ for the great reduction of the subapical area of the forewing and the absence of the submarginal spots of the hindwing. In the ♀ the spot between the 2. median and the submedian of the forewing is placed transversely and is usually united with a longitudinal spot placed before the submedian; the posterior basal spot is extended basad as far as the hindmargin of the wing; the discal and submarginal spots of both wings are mostly very large; sometimes the white patches occupy the greater part of the wing.

alexandrae. **P. alexandrae** *Rothsch.* (5 a, b). A wonderful species from New Guinea only recently discovered by A. S. Meek, whose ♀ is the largest of all known butterflies. Body black; head small; breast red; abdomen very long, especially in the ♂, in the latter yellow, in the ♀ grey-yellow, the base black. Neuration similar

to that of *victoriae*, but the 3. subcostal of the forewing branching off proximally to the apex of the cell. Wings of the ♂ velvety black, on the forewing a broad costal stripe and a still broader hindmarginal stripe enclosing the black scent-spot, on the hindwing a broad submarginal band, which at the costal and hindmargins is continued to the base, and a broad cell-streak, green-blue, in bred specimens more green than blue; both wings ong, lower angle of the forewing completely rounded off, hindw ng elongate-ovate. Underside blue-green, the forewing yellowish, the veins, the greater part of the cell of the forewing and the margins black, as are also on the forewing some stripes between the veins. The ♀ brown-black; forewing up to 135 mm long, with 2 rows of grey-white spots in the distal half and 2 spots in the cell; hindwing elongate-ovate, with large yellow-grey, browned wedge-shaped spots; beneath with the spots yellowish. The full-grown larva when at rest measures over 12 cm according to S. MEEK; it is velvety black with straight, ruby-red spines, and bears in the middle of the body a broad cream-coloured transverse band. — In the north-east part of British New Guinea, in low situations. A number of specimens of both sexes were taken. The butterfly flies high in the air and is not easy to catch. The species was originally described from a ♀ killed by the collector with gun-shot.

P. priamus. Stalk of the subcostal fork of the forewing short, 3. subcostal branching off several mm. proximally to the upper angle of the cell. ♂ before the hinder angle of the forewing with a long brand, which consists of small scent-scales and larger dentate scales covering them; a broad costal stripe, a narrower stripe (sometimes wanting) running along the distal and hindmargins, as well as the hindwing, green, blue or orange; hindwing mostly with black discal spots and often with gold-yellow submarginal ones; beneath the forewing spotted; hindwing yellow, spotted with black at the sides. Wings of the ♀ brownish black, with very variable grey-white, sometimes yellowish spots; as original markings we have on the forewing a cell-spot and on both wings two rows of spots between cell and distal margin, the upper of these spots on the forewing and mostly all the spots of the hindwing united in pairs into long patches, sometimes the forewing without spots. Larva black, with one or two white oblique stripes, the spines red with black tips or black with yellow rings. Pupa grey-yellow, gold-yellow or green. The earlier stages, most commonly to be found during the rainy season, are especially abundant in the neighbourhood of the coast. The butterfly mostly remains in the tops of trees, round which it circles with a sailing flight; when the ♀ is in search of the low-growing food-plant of the larva, the ♂ mostly follows it; both sexes also visit flowering trees and shrubs. The butterfly is purely Papuan; it inhabits in a number of geographical forms the Moluccas, the Key and Aru Islands, New Guinea with the neighbouring islands, the Bismarck and Solomon Islands and Australia southwards as far as the northern part of New South Wales. — **lydius** *Fldr.* (3 c). ♂: markings of the forewing above and the hindwing orange, green in an obliquely reflected light, those of the underside green, the cell-spot of the forewing large; cell of the hindwing beneath only distinctly edged with black posteriorly. ♀ for the most part grey-white, the cell-spot occupies almost the whole cell on both wings. Halmahera, and Ternate (fide WALLACE). — **croesus** *Wall.* (3 b, c). ♂ as in the preceding subspecies, but on the underside the green cell-spot of the forewing and the gold-yellow area placed before the cell of the hindwing smaller and the cell of the hindwing entirely margined with black; newly emerged specimens are green as in *lydius;* the harpe of the claspers in *lydius* and *croesus* much shorter than in the other forms of *priamus*, dorsally to the base in *croesus* with a pointed tooth, which is only indicated in *lydius*. ♀ with much reduced grey-white spots on the forewing, the cell-spot often absent; the wedge-patches of the hindwing are separated by rather broad brown-black vein-stripes, and are more or less yellow on the under surface, but mostly not of such pure yellow as the submarginal spots, which mostly have also a yellow tone on the upper surface. Larva on an Aristolochia which grows in sago-palm swamps; it bears on each side two white oblique stripes. Probably the larva of *lydius* likewise lives in such inaccessible places, which would explain why the butterfly is comparatively rarely taken. *P. croesus* only occurs on Batjan; in WYTSMAN'S Gen. Ins. RIPPON erroneously gives Amboina also as locality. FRUHSTORFER designates as ab. **lydioides** a ♂ whose costal band has a fiery carmine-red tone of colour and on which the costal and discal spots of the forewing beneath are coppery. The specimen has probably been longer exposed to the influence of the weather; also old specimens in collections are more fiery than fresh ones. Under similar conditions the green forms of *priamus* often acquire a bluish tint. — **aesacus** *Ney* (= obiana *Rebel*) inhabits Obi (= Ombira). In the ♂ a broad costal stripe of the forewing and a narrow stripe running along the distal and hindmargins green-blue like the hindwing; the latter above with golden, beneath with golden and black spots before the distal margin, the cell not margined with black. Ground-colour of the ♀ deeper black than in most of the *priamus*-forms, also the upperside of the abdomen rather strongly suffused with black; cell-spot of the forewing large, deeply excised distally; the distal area of the hindwing extending nearly to the cell, the black spots of the latter mostly small, the veins only very narrowly black. The occurrence of this blue-green (♂) form on Obi, of the blue *caelestis* on the Louisiades and of the green-blue *miokensis* on Mioko is a sufficient proof that the green forms do not belong to one species and the blue to another, but that they are all geographical developments of a single species. — **priamus** *L.* (♀ = panthous *L.*), from Amboina, Saparoea and Ceram (no *priamus*-form is yet known from Buru and the Banda Islands). A large form. ♂: the two stripes of the forewing and the hindwing green; median vein of the forewing without green scaling; hindwing above always with two or more black submarginal spots, beneath with a complete row of these spots, the cell anteriorly and usually also distally margined with black, and more rarely also posteriorly; the number and size of the gold spots variable,

lydius.

croesus.

lydioides.

aesacus.

priamus.

but the subcostal gold spot always present. ♀ without white spot in the cell of the forewing, the discal and submarginal spots of both wings reduced; the latter on the hindwing more or less strongly shaded with black-brown, the margin of the wing broadly black-brown and the black-brown discal spots large; the grey-white wedge-spots
hecuba. do not reach the cell either above or beneath. — **hecuba** *Röb.*, from Koer, Tiandoe and Key. ♂: in addition to the sides of the mesothorax a lateral spot on the metasternum is also red; forewing above with green scaling on the median, often also on the radials; hindwing above always with black discal spots, usually 3; beneath the black discal line of the forewing broader than the green submarginal line, the cell of the hindwing anteriorly edged with black, the black discal spots emarginate, the posterior ones usually truncate, the golden subcostal spot never (?) absent, but sometimes only indicated. ♀ brownish black, the white markings very sparsely shaded with blackish, rarely as dark as in specimens from Aru; cell-spot of the forewing mostly large, as long as broad or longer, rarely broader than long; the first three wedge-spots of the hindwing above and beneath pointed, rarely reaching the apex of the cell, the cell only sometimes with a white dot; sides of the prothorax red. A ♀ taken by H. Kühn has on the upperside of the forewing only 2 small white spots; they are placed between the
arruana. subcostals. Larva usually with a white oblique stripe. — **arruana** *Fldr.* Not differing constantly from New Guinea specimens, the ♂ especially cannot be recognised with certainty. The black discal band of the forewing of the ♂ beneath is broad and generally connected with the black hindmargin of the wing; the black discal spots of the hindwing are never absent above and are mostly very large beneath, the 2. spot is usually broader than the green spot placed distally to it, the yellow anal area has mostly a black spot, the subcostal gold spot is wanting in most specimens. In the ♀ the white markings of the upper surface of both wings are strongly shaded with blackish, sometimes also beneath partly suffused with blackish. Bluish ♂♂, probably discoloured under
cumaeus. the influence of moisture, have received the name **eumaeus** *Rippon.* We have also similarly coloured ♂♂ from New Guinea and they are doubtless found everywhere among the green forms of *priamus.* A very strikingly
chrysospila. coloured small ♂, ♂-ab. **chrysospila** *Rothsch.*, is in the collection of the Tring Museum: upper surface of the hindwing without black spots, on the contrary with 4 brown submarginal spots, of which the 3 upper ones have a large golden dot, in addition a large golden subcostal spot is present. Beneath all these spots are larger than above, also the 4. submarginal spot has a yellow centre; on the forewing no black discal band, only a black spot in the subcostal fork; on the hindwing only 2 small black spots between the costa and the 1. radial, cell not margined with black. The specimen gives one quite the impression of a separate species; the genitalia are as in *arruana.* The larvae and pupae were found by Ribbe only in the vicinity of water-courses and at the sea-coast, but on dry
poseidon. ground. — **poseidon** *Dbl.* (= pegasus *Fldr.*) (2 a). In New Guinea and on the smaller islands off its coast it does not seem to have yet formed definable subspecies. No single character is even moderately constant in the individuals from any one of the different faunistic districts. It is true that in the ♂♂ from British New Guinea the green cell-area on the underside of the forewing is more frequently reduced to a rounded spot and the black markings of the underside of both wings are more often enlarged than in the ♂♂ from the northern and western parts of the island, and that among the ♀♀ from British New Guinea we find more commonly specimens with reduced white markings and among those from Waigeu a larger percentage have a white spot in the cell of the hindwing than is the case in other districts, yet these differences are so very uncertain that we regard all the specimens from Misol, Salawatti, Waigeu, Dutch, German and British New Guinea, the islands in Geelvink Bay, the D'Entrecasteaux Islands, Trobriand and the small islands in the Torres Straits as belonging to one very variable subspecies. According to Rippon (in Wytsman's Gen. Ins.) *poseidon* also occurs on the Tenimber Islands; the statement, like so many in Rippon's work, is founded on a mistake; no *priamus*-form occurs on the Tenimber Islands. The green median line in the forewing of the ♂ is apparently never entirely absent, but in one of our specimens it is only represented by 3 green scales; in contradistinction to the Aru and Key ♂♂ the black discal band of the hindwing beneath is mostly narrow, sometimes however it is broader than the green submarginal band, but in this case the last spot but one of this band is usually rounded; the discal spots of the hindwing are also mostly rounded, the cell is not usually distinctly edged with black anteriorly and most specimens have
cronius. no black spot in the yellow anal area. In ♂-ab. **cronius** *Fldr.* the black discal spots are wanting on the upper
triton. surface of the hindwing, and in ♂-ab. **triton** *Fldr.* the hindwing has some gold spots. In the ♀ many specimens have fully as much white as the Key ♀♀; in many the white spots are shaded with blackish; in one of our specimens from the mountains of British New Guinea with the colour of the wing evidently not yet fully developed the markings above and beneath are yellow, partly sprinkled with white; this specimen is even more yellow
kirschi. than ♀-ab. **kirschi** *Oberth.*, in which the cell-spot moreover is edged with metallic green. Not infrequently a cell-spot is wanting on the forewing and only a row of patches is present between cell and distal margin: ♀-ab.
boreas. **boreas** *Fruhst.* In contrast to this there are specimens in which the cell-spot and the discal spots between the median veins are developed, but the other spots of the forewing partly reduced and partly obsolete. The ♀♀ with
archideus. a spot in the cell of the hindwing, which are particularly common on Waigeu, are ♀-ab. **archideus** *Gray.* The
brunneus. specimens with slight traces of spots on the forewing or without spots are ♀-ab. **brunneus** *Rothsch.* (3 a); this form is especially common on Trobriand, the D'Entrecasteaux Islands and in British New Guinea; from the small Engineer Islands, lying in the prolongation of the south-east point of British New Guinea, we have 5 ♀♀, of which 4 belong to ab. *brunneus*, whilst in the fifth specimen the white spots are certainly present, but small
valentina. and strongly blackened. Dwarfed specimens of both sexes are ab. **valentina** *Vaill.* None of these forms are con-

fined to a fixed locality. The butterfly is very common in most districts. Tubercles of the larva red with black tips; a white oblique band on the 7. segment; fork on the neck red. Egg brown (KUBARY). — Whether **boisduvali** *Montr.* (= oceanus *Fldr.*), from Woodlark, is different from *poseidon* we cannot say, having seen no specimen of it. The description agrees with *poseidon;* the insect appears to be very rare or very local. A. S. MEEK, who has twice collected on Woodlark, saw only a single specimen, a ♀. — **pronomus** *Gray.* The ♂ with a green median line on the forewing; the cell-spot of the forewing beneath does not reach the base and in most specimens is confined to the distal half of the cell; the hindwing bears (always?) a subcostal gold spot; on the underside the cell is posteriorly and often also at the apex edged with black and the distal margin of the wing is somewhat more broadly black than in *poseidon.* In the ♀ the white markings of the forewing are usually only slightly dusted with black, the cell-spot is at least of medium size and the submarginal spots are always large. Cape York. The specimens from Thursday Island agree partly with *pronomus,* partly with *poseidon.* — **euphorion** *Gray* (= cassandra *Scott*) (1 b) inhabits northern Queensland with the exception of the most northern districts. ♂ without green median stripe on the forewing, the green submarginal band irregularly undulate, the green markings of the underside very much reduced, especially the cell-spot, the cell of the hindwing completely or almost completely surrounded with black, the black discal spots large, the black margin broad. In the ♀ the white markings smaller, on the upperside of the hindwing strongly shaded with black; abdomen above greyish black, prothorax laterally broadly red. Larva brown, without white oblique band, the tubercles black with a yellow ring, the dorsal tubercles of segment 7 yellow with black tip. Pupa as in the preceding forms above yellow, beneath brownish yellow. The ♂♂ are commonly found in pairs, one ♂ following the other. Both sexes visit by preference the flowers of wild melons in open spaces in the woods. — **richmondia** *Gray* (= richmondii *Schneid.*). A small form, which occurs in southern Queensland and northern New South Wales. ♂ similar to *euphorion*-♂, the posterior green band of the forewing not reaching the base of the wing, commonly reduced to a submarginal band, which is sometimes very short. In the ♀ the green median line of the thorax absent or only indicated; the prothorax less extended red than in *euphorion;* the patches reduced as in that subspecies, but the wedge-spots of the hindwing longer and the 2. submarginal spot produced into a line basad behind the subcostal, so that an outwardly thickened semicircle or a hammer-shaped patch is formed. Larva somewhat paler than in *pronomus,* with slightly greenish tinge, the fork on the neck (osmaterium) greenish yellow, the tubercles much as in the preceding form; on Aristolochia praevenosa. The freshly emerged larva has black spinose tubercles, only the dorsal tubercles of segment 7 are almost entirely yellow. Pupa vivid green. The egg laid on the underside of a leaf. — **caelestis** *Rothsch.* (3 a). Likewise small. ♂ blue, resembling small specimens of *urvillianus,* the distal margin of the hindwing above and beneath more broadly black, especially anteriorly, and strongly dentate; on the under surface the cell-spot of the forewing long, the hindwing with dense metallic scaling before the costa in the basal half, the cell only edged with black anteriorly and but very narrowly, the yellow anal area extended almost to the cell, the black spot in it, if present, smaller than the preceding spot. ♀: ground of the wings darker than in *urvillianus,* the two anterior black discal spots of the under surface of the hindwing consequently less distinctly brought out; the patches of the upper surface dusted over with blackish, the cell-spot of the forewing large, longer than broad, produced basad, distally once or twice excised or scalloped, between the 3. radial and the submedian fold 3 elongated discal patches, of which the middle one is the largest, the submarginal and the anterior discal spots similar to those of *urvillianus;* the brown-black marginal band of the forewing broader, especially the wedge-spot placed between the 1. and 2. radials distally more deeply scalloped. Pupa above between the wing-cases yellow. St. Aignan, Sudest and Rossel, Louisiades. The occurrence of a blue form on these islands lying in the direct prolongation of the south-east point of New Guinea is very striking. — **bornemanni** *Pagenst.* ♂ green; the band running along the hindmargin of the forewing only slightly developed; the hindwing in the basal half, especially in the cell, more or less sparsely scaled with green, the black submarginal spots small. ♀ very similar to *poseidon*-♀♀, with well developed white markings, but paler blackish brown, therefore the two anterior black discal spots of the hindwing beneath more distinct; the white markings of the upper surface, especially on the hindwing, dusted over with blackish, the wedge-spots of the latter proximally pointed and not reaching the cell. New Pomerania (= New Britain) and French Islands. — **miokensis** *Ribbe,* from Mioko, is green-blue (♂). We have only seen bred specimens, and draw attention to the fact that bred specimens of the next subspecies killed too soon have also a greenish tone. — **urvillianus** *Guér.* (2 b). ♂ blue; hindwing similarly as in *bornemanni* more or less black from the base to the middle or beyond, discal spots above and beneath large; the cell in the specimens from the Solomon Islands mostly strongly edged with black, which is rarely the case in the specimens from New Hanover, also in individuals from the Solomons the black spot placed in the yellow anal area almost always larger than the preceding one; specimens with a subcostal gold spot are ♂-ab. **flavomaculata** *Ribbe.* ♀ pale blackish brown, the white markings mostly small and strongly dusted over with blackish; the wedge-spots of the hindwing pointed and the vein-stripes separating them mostly broad, the patch placed in the 2. marginal cell commonly hatchet-shaped as in *richmondia.* New Hanover, New Mecklenburg (= New Ireland) and Solomon Islands. The larva black or grey-brown, with red tubercles, which are black at the tip, the tubercles of the prothorax without red, a white oblique band at the sides. Pupa above yellow. This widely distributed butterfly is no rarity; it is among the first butterflies which the traveller notices on the wooded shores in the tops of the trees.

boisduvali. *pronomus.* *euphorion.* *richmondia.* *caelestis.* *bornemanni.* *miokensis.* *urvillianus.* *flavomaculata.*

chimaera. **P. chimaera** *Rothsch.* (4 b). Most nearly allied to *P. tithonus.* The head in both sexes small. Forewing of the ♂ similarly marked to that of *tithonus;* the distribution of colours on the hindwing different, as the figures show; abdomen yellow, beneath with rather rough hairs, above with black spots laterally. The ♀ remarkable before all other Papilios in that the rough-haired abdomen is ringed with black; the white spots of the forewing are very variable in size and number. — This easily recognised species was discovered by A. S. Meek at the southern slopes of the Owen Stanley Range in British New Guinea, at the upper Aroa River. The butterfly was very rare there, but Meek captured a considerable number, partly with the help of natives. The greater number of the specimens were taken on a single flowering tree on which the butterfly settled one at a time. Meek afterwards caught some more specimens at the north-east side of the range, at the upper course of the Mambaré River.

tithonus. **P. tithonus.** Stalk of the subcostal of the forewing short, the 3. subcostal branching off proximally to the apex of the cell. Abdomen of the ♂ with black lateral spots, forewing without brand, with 3 gold-green longitudinal stripes, of which the 1. and 2. are distally widened; hindwing elongated, the anterior half and 2 spots at the anal angle silky golden, distally and posteriorly golden green, the abdominal margin broadly black and the distal margin narrowly black, 3 black discal spots; underside of the forewing for the most part golden green, with a large black area at the apex of the cell; the hairs placed on the abdominal fold very long. ♀ similar to *poseidon*-♀, but the hindwing with the abdominal margin longer, the costal and distal margins evenly rounded together, the lower median branching off much more distally from the cell, the black marginal band broad and not undulate, the black discal spots round. Earlier stages not known. 2 subspecies.
waigeuensis. — **waigeuensis** *Rothsch.* ♂: the part of the median band placed in the cell of the forewing narrow; cell of the hindwing for the most part golden. ♀: spots of the forewing large, cell-spot of the hindwing shorter than
tithonus. broad. Waigeu. — **tithonus** *Deh.* ♂: the median band of the forewing broader in the cell than in the preceding form; the 2. and 3. black discal spot of the hindwing larger; less than the half of the cell of the hindwing golden. ♀: spots of the forewing much reduced, on the other hand the white area of the hindwing enlarged, the cell-spot of the hindwing longer than broad. Onin Peninsula, Dutch South-West New Guinea. Doherty found a few specimens in the hills at Kapaur in December and January.

P. goliath. Forewing broader than in *P. priamus,* the lower angle less rounded, especially in the ♂; the 3. subcostal near the end of the cell; the stalk of the 4. and 5. subcostals longer than in *priamus.* Forewing of the ♂ without brand, velvety black; a broad costal stripe and also a large triangular area, which extends from the hindmargin costad but does not enter the cell, are green; hindwing rounded, gold-yellow, the veins and 3 black-centred submarginal spots green, the abdominal area and the distal margin black. Beneath the forewing is gold-green, the veins and margins as well as a row of discal spots black; hindwing gold-yellow, the abdominal area from the cell to the scent-organ and the distal margin with the exception of the extreme edge, green. The ♀ resembles in pattern certain *priamus*-♀♀; the eye as in the ♂ is conspicuously margined with white posteriorly; the forewing either only with traces of patches, or there are a large divided cell-patch, a row of submarginal spots and several discal spots present, the hindwing has a broad yellowish white discal area, in which is placed a row of rounded white discal spots; abdomen above grey-yellow, laterally and beneath pure yellow, the 1. segment as well as the base of the others laterally and beneath black. This insect, which is still very rare in collections, is distributed over the whole of New Guinea, but is apparently local. It has been bred more than once, but nothing appears to have been published as yet about the larva and pupa.
goliath. — **goliath** *Oberth.* (7 a) doubtless came from Waigeu; the specimen from which the species was described was found in a collection which was left without exact data as to locality. As the same collection contained a ♀ of *P. tithonus* which belongs to the Waigeu, not the mainland form, we may probably take it that the collection was made on Waigeu. In the ♀ of *goliath* the cell of the forewing has a trilobate spot and the discal area of the hindwing above is suffused with blackish. We place here provisionally a ♂ which comes either from Waigeu or the coast-districts of Geelvink Bay; it is smaller than the ♂♂ known to us from German and British New Guinea; the gold-yellow spot placed behind the 2. median of the hindwing is larger, the costal margin of the forewing beneath is more broadly black and the black patch placed in the subcostal fork is
atlas. larger. — **atlas** *Rothsch.*, from Kapaur, Dutch South-West New Guinea. Only 2 ♀♀ known, which were found by W. Doherty in January and February, 1899. Cell-patch of the forewing broken up into spots; behind the 2. median a discal spot, on the underside before the 2. median 2 discal spots, besides these a submarginal spot; the discal area of the hindwing above grey-white, thickly shaded with black, beneath distally yellow
supremus. and proximally white. — **supremus** *Röb.* (= schoenbergi *Röb.*, elisabethae-reginae *Horv. & Mocs.*, goliath *Horv. & Mocs.*) (7 a). The best known form. The ♂ varies somewhat in the extent of the green areas of the forewing and the size of the submarginal spots of the hindwing. The ♀ has on the forewing above and beneath only 2 spots between the 1. and 2. medians; the discal area of the hindwing above is mostly less shaded with black than in the preceding forms and more uniform yellow, especially beneath. German New Guinea. —
titan. **titan** *Grose-Smith* is the subspecies from British New Guinea. The ♂ differs from *supremus* by the somewhat narrower black distal margin of the hindwing; on the under surface of the forewing the black discal spot placed

behind the 2. median is only indicated; the hindwing bears above 3 submarginal spots like the other forms, beneath, however, the 2. spot is wanting in the only known specimen, whilst one is present in each of the 1., 3. and 4. marginal cells. In the ♀ the spots of the forewing are partly obsolete, partly very much reduced; the yellow-white area of the hindwing is similar to that of *supremus*, but is less yellow beneath. 1 ♂ in coll. H. Grose-Smith and 2 ♀♀ in the Tring Museum, from the south side of the Owen Stanley Range.

P. paradisea. The 3. subcostal of the forewing from the apex of the cell (or quite near to it), the stalk of the subcostal fork long. Forewing of the ♂ without brand, with 2 broad golden green longitudinal stripes and a narrow hindmarginal stripe; hindwing triangular, produced into a tail, golden, this area distally and posteriorly margined with green, abdominal margin broadly black; the hairs on the abdominal fold of the hindwing long, yellowish white. ♀: the 2. median of the hindwing branching off at the same height as the 1. radial; the spots of the forewing very variable, the cell-spot rarely as long as broad, often entirely absent; the black discal spots of the hindwing round, varying in size and number; sometimes a white spot in the cell of the hindwing. A reliable detailed description of the entire life-history is still wanting. Egg spherical, light yellowish, much larger than that of *poseidon*. Larva velvety black, without markings, the tubercles from the first stage onward fiery red, later partly black, those on the 4. and 5. segments always black; nuchal fork vivid yellow, the slit itself red. Full fed in 4 or 5 weeks. Pupa not on the food-plant, but on shrubs and trees at about 1 m above the ground; more slender than the *poseidon*-pupa, above lighter yellow, beneath and laterally darker brown. The butterfly emerges in 5 to 6 weeks. It flies at the sea-coast and in hilly country. — **paradisea** *Stgr.* (= schoenbergi *Pagenst.*) is the form from German New Guinea, which the last few years has come to Europe in considerable numbers. Strongly golden ♂♂ are ♂-ab. **auriflua** *Fruhst.* ♀♀ which have a white spot in the cell of the hindwing are ♀-ab. **punctata** *Hagen* (the specimen erroneously figured by Rippon in Icon. Ornith. as *punctata „Rothsch.“* is a cripple without this cell-spot), whilst ♀♀ with little or no white in the cell of the forewing are ♀-ab. **caliginosa** *Fruhst.* — **flavescens** *Rothsch.* Only 1 ♀ known, from Etna Bay, Dutch South-West New Guinea. Forewing above with 2 small discal spots, of which the spot behind the 2. median is larger than the one placed before this vein; in *paradisea* the anterior spot is always the larger, moreover this subspecies has usually another spot before the 1. median; the light area of the hindwing of *flavescens* is more yellow above and beneath. *paradisea. auriflua. punctata. caliginosa. flavescens.*

P. meridionalis *Rothsch.* (6 c). ♂ similarly marked to *paradisea;* hindwing much smaller, the hindmarginal area not projecting in a lobe, the narrow tail widened before the tip, the cell much narrower, the 3. radial and 1. median not stalked; the forewing distally to the middle with large black area (much as in *tithonus*). ♀: the discal markings purer white; the cell-spot of the forewing about as long as broad, always 3 discal spots present; the distal margin of the hindwing more broadly black, the white area in and behind the cell extended further towards the base, the inner margin of the area therefore more oblique than in *paradisea.* — British New Guinea: Milne Bay and Mailu. So far as we know, only 8 ♂♂ and a somewhat larger number of ♀♀ are known, of which the Tring Museum has selected a series of 4 ♂♂ and 7 ♀♀; the insect varies but little. *meridionalis*

P. brookiana. Pronotum and occiput red. Forewing long, cell truncate, the lower angle acute; in the ♂ a band consisting of 7 metallic green wedge-spots between cell and distal margin; hindwing small, the cell narrow, the band of the forewing continued over the hindwing, the abdominal margin bent over above, forming a scent-fold. ♀ paler than the ♂; the discal band of the forewing anteriorly more or less extended white; hindwing with white or grey submarginal spots, both sexes beneath with such spots, which however are larger in the ♀ than in the ♂. Malayan. Nothing is yet known about the earlier stages. The butterfly is a woodland species, which is generally not rare in the hills and mountains of Malacca, Sumatra and Borneo. The ♀ follows the ♂ and rests on its back during copulation. When the insect is feeding at flowers the wings have a buzzing motion as in a Sphingid (Skertchley). According to Martin on the contrary *brookiana* is never found at flowers in Sumatra, but often settles on moist places on the roads and on rubbish heaps (dung and kitchen refuse) near the houses, which the yellow species never do. — **albescens** *Rothsch.* (7 b). The ♂ has always white submarginal spots on the underside of the forewing. In the ♀ the white spots on the upperside of the forewing and the underside of both wings are very large. Perak. — **natunensis** *Rothsch.* ♀: a transition-form between *albescens* and *brookiana*, nearer to the latter, but the white markings larger. Bunguran, Natuna Islands. — **brookiana** *Wall.* (7 c). ♂: forewing beneath usually without submarginal spots. In the ♀ the white spots on the forewing beneath widely separated except the anterior ones, and *albescens. natunensis. brookiana.*

the spots of the hindwing not confluent although sometimes touching one another. Borneo; Balabac. —
trogon. **trogon** *Voll.* (♀ = eleanor *Walk.*) (7 c). ♂ not distinguishable with certainty. ♀ similar to the ♂, less white than in the other forms, above almost without white, and beneath the anterior spots of the forewing also reduced. East and West Sumatra, all the year round in the plain and the foot-hills.

trojana. **P. trojana** *Stgr.* (5 b). ♂: metallic spots of the forewing shorter than in *brookiana;* hindwing with a band placed outside the cell, beneath the submarginal spots, as also in the ♀, further removed from the margin than in *brookiana.* The blue-grey scaling on the upper surface of the hindwing of the ♀ only sparse in and behind the cell, on the other hand on the disc beyond the cell condensed into a band. — Palawan; still rare in collections. A sojourn on this island is very unpleasant and dangerous, especially on account of the many doubtful characters who have taken refuge there from the Philippines. So far no collector has succeeded in reaching the mountains.

P. hypolitus. Cell of the hindwing distally widened, especially in the ♂; forewing with white vein-stripes. ♂: abdomen above dark yellow and black; hindwing above black, with a row of yellow submarginal spots which are also present beneath, the under surface between these spots and at the margin black, otherwise silky grey-white or yellowish white. ♀ on the hindwing between distal margin and cell with large spots, the anterior ones yellow, the posterior grey, all except the first enclosing black discal spots, cell entirely black or with a small apical spot; beneath as above, but the cell of the hindwing always with a large grey-white spot and the forewing more strongly streaked. Earlier stages not known. According to Ribbe the butterfly occurs on Ceram at the coast wherever there is underwood. The Moluccas and Celebes; several
hypolitus. geographical forms. The insect is not yet known from Buru. — **hypolitus** *Cr.* (= panthous *L.* partim, pandarus *Houtt.*, remus *F.*, antenor *Well.*, hippolytus *Esp.*, hippolythus *Esp.*) (8 a). ♂ grey-white on the under surface of the hindwing. ♀: hindwing beneath with a large cell-spot, the three posterior marginal cells white,
antiope. only yellow between the black discal and submarginal spots. Ceram and Amboina. — **antiope** *Rothsch.* Only ♂♂ are known to us. On the whole smaller than *hypolitus;* the vein-stripes of the forewing above less distinct; on the underside of the hindwing the lower outer angle of the 2. yellow spot more produced, the interspace between the 2. and 3. spots consequently smaller, the black spot placed before the 3. radial larger, the white spot before the 2. radial always very small and the median nervure more narrowly black. Morty (= Morotai), a number of ♂♂ in the Tring Museum, collected by Dumas. According to Wallace *hypolitus* also occurs on Halmahera, and Pagenstecher records the insect from Halmahera and Ternate. As in the other
sulaensis. subspecies the ♀ of *antiope* is probably more strikingly different from *hyp. hypolitus* than the ♂. — **sulaensis** *Stgr.* Hindwing beneath in ♂ and ♀ and in the ♀ also above more extended yellow than in *hypolitus.* The
cellularis. cell-spot of the hindwing of the ♀ beneath small. Sula Islands: Mangola and Besi. — **cellularis** *Rothsch.* (= celebensis *Stgr.* nec *Wall.*). ♂ as in *hypolitus;* the semitransparent vein-stripes on the upper surface of the forewing only very sparsely scaled with white; the 2. yellow spot of the under surface of the forewing mostly broader than long. ♀ also above with cell-spot on the hindwing. South and North Celebes; Talaut. According to Piepers also on Saleyer (is this correct?).

darsius. **P. darsius** *Gray* (9 b, c). In ♂ and ♀ the abdomen above brownish black; the golden area of the hindwing cut off straight towards the base, the cell at least to the base of the 2. median black, the golden cell-spot sometimes dot-like; the last golden patch of the ♂ the largest, in the ♀ the black discal spots touching one another; the white stripes at the lower median of the forewing of the ♀ far removed from the cell.
cambyses. Sometimes the ♂ with several black discal spots in the yellow patches: ♂-ab. **cambyses** *Ehrm.* — Ceylon, almost everywhere in hilly country, but also in the plains in open and wooded districts; the butterfly is fond of feeding at heliotrope. Larva dark purple-brown, with blackish streaks; lateral band pale red. Thwaites often observed how a pair danced up and down in the air, the ♀ always remaining about 2—3 ft. above the ♂.

P. vandepolli. Breast without red; abdomen entirely or for the most part black. ♂: cell of the hindwing broad, the abdominal area and the base of the wing broadly black, the black distal margin likewise broad, the golden cell-spot obliquely truncate, its proximal margin nearly forming a prolongation of the 2. median vein. ♀: the posterior 2 or 3 pairs of white vein-stripes of the forewing placed at a distance from the cell; the golden area of the hindwing proximally straightly truncate or almost, not reaching to the middle of the cell. Egg pale
honrathiana yellow. Sumatra and Java. — **honrathiana** *Martin* (8 b) occurs in the hilly country of North-East Sumatra. Body entirely black apart from the thin red collar, rough hairy. In the ♀ cell of the forewing at the apex with
vandepolli. an M-shaped white mark, the vein-stripes thin, the last 3 pairs far removed from the cell. — **vandepolli** *Snell.* (8b).

Abdomen laterally and beneath grey-yellow and black, less rough, above in the middle brown in the ♂. The white vein-streaks of the ♀ broader than in the preceding subspecies, the anterior one of the third pair counted from behind near to the cell or reaching it, apex of the cell white. Mt. Gedé, Preanger, Java, 4—5500 ft.

P. criton. Collar and breast red; abdomen beneath and laterally much more extended yellow than in *plato* and the forms of *haliphron*. ♂: forewing above and beneath without vein-stripes or there are white vein-stripes present beneath; the golden area of the hindwing consists of a large cell-spot and 6 large discal spots, the last discal spot the longest, very much longer than the black marginal band is broad, the 1. spot longer than broad, all or at least the posterior ones distally emarginate, the cell-spot obliquely truncate, occupying the half of the cell or somewhat more, longer anteriorly than posteriorly. ♀ variable; the white streaks at the 2. median of the forewing, if present at all, far removed from the cell; the golden area of the hindwing almost straightly truncate, the spot placed behind the 2. median not prolonged basad beyond the point of origin of this vein, often absent; the black discal spots, especially the central ones, rounded, above rarely completely merged together, beneath always smaller; the black marginal band, which is deeply incised at the veins, narrower than the yellow central spots are long, measured from the cell to the black discal spots. Larva similar to that of *haliphron*, somewhat more brightly coloured. Pupa greenish. Northern Moluccas and Obi, rather common; rare on Celebes. — **criton** *Fldr.* (11 a, b), from Batjan, Ternate, Halmahera and Morty, rarely has in the ♂ white vein-streaks on the under surface of the forewing. The ♀ occurs in 3 principal forms: ♀-f. **androgyna** *form. nov.* has neither above nor beneath white vein-stripes or the stripes are only faintly indicated on the upperside and more strongly beneath; in ♀-f. **oberthueri** *Rothsch.* the apex of the cell and the vein-stripes are almost pure white above and beneath, the yellow area of the hindwing is golden as in the preceding ♀-form; ♀-f. **felderi** *Rothsch.* has faint vein-streaks above and the central area of the hindwing is not golden but pale cream-colour. — **critonides** *Fruhst.*, from Obi, is not constantly different from *criton*. ♂: forewing beneath often with white vein-stripes (in 4 of our 7 ♂♂), the cell-spot of the hindwing mostly less obliquely truncate than in *criton*. In the ♀ the spot placed before the 1. radial of the hindwing always small, no yellow or cream-coloured discal spot before the subcostal; the black discal spots completely merged together, so that above only quite small yellow submarginal spots are present. The 3 known principal forms of the ♀ are: ♀-f. **melas** *form. nov.*, forewing without distinct vein-stripes, or these at least above weakly developed, central area of the hindwing above yellow; in ♀-f. **cinna** *Fruhst.* 1/3 of the cell of the forewing and the broad, proximally united vein-stripes are almost pure white and the central area of the hindwing is golden above; ♀-f. **clara** *form. nov.* has even more white than *cinna* and the central area of the hindwing is cream-coloured above. — **celebensis** *Wall.* The type (a ♂ from „Macassar") of this form is in the collection of H. Grose-Smith. Dr. L. Martin received a second specimen from his collectors from Putannani, South Celebes, which he has handed over to the Tring Museum. These two specimens — the only ones which I have seen — are very similar to the *criton*-♂ from the northern Moluccas. The abdomen, however, is black, with narrowly yellow margins to the segments beneath; the claspers almost entirely grey-yellow. Forewing beneath with distinct whitish grey stripes, which extend to the cell; the yellow area of the hindwing distally more deeply scalloped than in the other *criton*-forms. The ♀ from the Minahassa in coll. Staudinger mentioned in Novitates Zoologicae 1896, p. 64, probably belongs to *P. helena hephaestus*.

criton. *androgyna.* *oberthueri.* *felderi.* *critonides.* *melas.* *einna.* *clara.* *celebensis.*

P. riedeli *Kirsch* (10 a). This apparently very constant species is one of the rarer forms. Body similar to that of *criton*, but the abdomen more sparsely yellow, especially at the sides; both wings more elongated than in the allied species. ♂: forewing beneath with distinct but thin white vein-stripes, the pairs placed at the two median veins removed from the cell; the gold area of the hindwing much as in *criton*, but proximally cut off straight, the cell-spot much smaller, the posterior discal spots much longer and almost all the spots more deeply emarginate, the black hindmargin at the apex of the golden area and the black distal margin before the subcostal much narrower than in *criton*. ♀: forewing at the apex of the cell and distally to it white, this area produced into stripes at the veins, at the 1. median a white double stripe, which is remote from the cell; hindwing with dot-like cell-spot or the cell entirely black, 4 golden discal spots and behind this area a whitish grey spot; the black discal spots not completely merged together, but the yellow spots separated by them strongly scaled with black on the upper surface. — Sjerra, Timor Laut Islands, perhaps also on the other islands of this group.

riedeli.

P. haliphron. Abdomen black, with but little yellow scaling laterally and beneath, or entirely without yellow, in the ♀ brown above. The golden area of the hindwing in the ♂ with oblique edge basally, the black basal and hindmarginal area extending at least to the lower median, sometimes the whole cell black; the gold patches not distinctly emarginate distally, the middle ones truncate or rounded off, the distal margin very broadly black. The gold area of the ♀ mostly cut off straight in the cell, the black discal spots long, especially the posterior ones, mostly all joined to the marginal band, often so completely merged together with the latter that there

are no gold spots left in the broad marginal area. A geographically variable species, whose habitat extends from Celebes and Sumbawa eastwards. It does not occur on Lombok, whilst on the neighbouring island of Sumbawa
haliphron. it is rather abundant. — **haliphron** *Bdv.* (9 a). Breast red, the last ventral segments narrowly edged with grey-yellow, in the ♀ a grey-yellow patch at the lateral margins of the posterior segments. ♂: gold spot of the cell of the hindwing small or absent. ♀: the stripes at the submedian of the forewing above indistinct, the posterior stripe of the penultimate pair not reaching the cell, the cell proximally surrounded with white almost to the point of origin of the 2. median. South Celebes. So far no *haliphron*-form is known from North Celebes; also no relative is known from the Sula Islands. Dr. MARTIN bred a gynandromorphic specimen of *haliphron* whose left side
pallens. is female and the right male. This is now in the Museum at Tring. — **pallens** *Oberth.* (= bauermanni *Röb.*). Vein-stripes in ♂ and ♀ more strongly developed than in *haliphron*, the cell-spot of the hindwing larger, in the ♀ moreover the body and wings paler. Saleyer, common; Kabia. The name *bauermanni Röb.* is founded on specimens
pistor. from the island of Kabia; there appear to be no tenable differences. — **pistor** *Rothsch.*, from Kalao and Djampea. The ♂ not constantly different from *pallens;* the cell of the forewing beneath is mostly less extended white and the yellow scaling of the under surface of the abdomen is usually even more sparse. The ♀ has less white in the cell of the forewing; the cell-spot of the hindwing occupies less than half the cell, the black discal spots are shorter than in *pallens;* on the underside the middle of the hindwing is more distinctly yellow, sometimes almost as
naias. yellow as above, and the yellowish grey area extended beyond the cell is smaller than in *pallens.* — **naias** *Doh.* inhabits Sumba, Sumbawa, Flores, Larentuka, Adonara, Lomblen and Alor. ♂: the white vein-stripes are well expressed also above; the first gold spot of the hindwing large and at least as long as the second spot, the cell-spot lies along the front margin of the cell and is often so much widened that it occupies at least half the cell; round the cell 4 or 5 gold patches, beneath sometimes also a sixth more or less distinct; the white edging of the cell of the forewing beneath mostly extended to the point of origin of the 2. median; this edging in the ♀ still more prolonged towards the base, also above more extended than in the preceding subspecies. The ♀ also distinguished by the presence of 7 gold spots around the cell, the 1. spot small, very rarely wanting (in one of our two Larentuka ♀♀), the last more or less grey, the cell-spot mostly occupying two-thirds of the cell. The yellow scaling of the abdomen in both sexes more extended than in the preceding forms. The percentage of ♂♂ which have a large cell-spot on the hindwing is larger on Sumba than on the other islands, also the Sumba specimens
sambavana. have more commonly a 5. discal gold spot. The designation ♂-ab. **sambavana** *Doh.* may be applied to the ♂♂ in which this spot is present. The butterfly is common on Sumba at the coast and in the interior, also it appears
socrates. to occur abundantly on the other islands. — **socrates** *Stgr.* (12 a, b). Breast and collar entirely black or with very few red hairs; abdomen less extended yellow than in *naias.* The ♀ without gold spot before the subcostal on the hindwing and with quite narrow yellow streak behind the lower median, the black discal spots broadly
iris. united with the marginal band and all or almost all touching one another. Wetter. — **iris** *Röb.* (12 c). ♂: vein-stripes of the forewing above weak, beneath the stripes placed at the 2. median remote from the cell, the cell itself without distinct white edging; hindwing with small cell-spot, which is often absent, as well as 4 discal spots, often a still smaller spot is present before the subcostal and a streak behind the 2. median; pronotum and breast without red hairs. ♀: pale brown, collar and breast very rarely red, the vein-streaks dirty white, those placed at the 2. median above and beneath remote from the cell; the gold area of the hindwing small, consisting of a small cell-spot and 4 discal spots, commonly another small spot before the 1. radial and yet another behind the 2. median; in the broad marginal area no gold spots or only slight traces of them. Letti and Moa, common. —
ariadne. **ariadne** *Rothsch.* ♂: collar and breast red, the margins of the posterior abdominal segments beneath narrowly but distinctly yellow; vein-stripes of the forewing beneath purer white. ♀ likewise with red collar and red sides to the breast; the cell-spot of the hindwing and also the spots placed before the 1. radial and behind the 2. median
staudingeri. larger than in *iris.* Roma. — **staudingeri** *Röb.* ♂: forewing similar to that of *iris*, beneath with purer white stripes; hindwing almost as in *naias*, but always with 6 gold discal spots round the cell and the cell-spot more transversely truncate; the harpe similar to that of *iris*, almost symmetrical, whilst in the other *haliphron*-forms it is almost hook-shaped. ♀ with broader vein-streaks on the forewing than in *iris;* on the hindwing in addition to the cell-spot 6 gold spots, of which the first and last are much larger than in *iris* and *ariadne;* the median veins at least beneath accompanied by yellow-grey stripes, similar stripes or small submarginal spots also often
ikarus. on the radials. Collar and breast in ♂ and ♀ red. Loeang, Dammer and Babber. — **ikarus** *Fruhst.* (12 a, b). The ♂ not different from *staudingeri*, the vein-stripes of the forewing beneath and also the edging of the cell, however, are longer and broader in some specimens. This grey-white scaling in the ♀ apparently always more extended than in *staudingeri.* Selaru, Timor Laut Islands. — Larva of *haliphron* brown, the tubercles pale red, the lateral band dark whitish yellow. Pupa yellow-green.

plato. **P. plato** *Wall.* (11 a, b). Distal margin of both wings more strongly scalloped than in *haliphron;* collar red, breast black. ♂: forewing from the base to the point of origin of the 1. median black, then somewhat lighter; hindwing with large cell-spot and 6 large discal spots, the latter usually more or less emarginate distally, the cell-spot obliquely truncate in the prolongation of the 2. median; beneath the vein-stripes of the forewing very broad and somewhat effaced, the two stripes placed at the 2. median remote from the cell. ♀ in two forms,

a light and a dark, as in *criton* and *helena*. In both forms the forewing from the base to beyond the origin of the 1. median is black or black-brown; this area rather sharply defined. In the dark form, ♀-f. **nychonia** *form. nov.*, the distal half of the forewing is similar to that of the ♂, only the apex of the cell is somewhat lighter; the yellow area of the hindwing consists of a rather small, obliquely truncate cell-spot and 6 large discal spots; the black discal spots are rather small and separated from one another, but broadly united with the black marginal band. In the second female form, ♀-f. **chitonia** *form. nov.*, the vein-streaks of the forewing are very broad and above also very distinct, towards the base they are grey-white, as is also the apical third of the cell; the yellow area of the hindwing is cut off straight (not obliquely) basally; no spot before the submedian, on the other hand a larger spot behind the 2. median, the black discal spots completely confluent with one another and with the marginal band, so that in the broad black area thus formed only quite small yellowish spots are present; beneath the discal area is not golden. — Dutch and Portuguese Timor; rare in collections, like many of the Timor species. The island, which possesses a vegetation recalling that of North-West Australia, is very unhealthy in the rainy season, and in the long and very arid dry season only very few insects are to be found. *nychonia.* *chitonia.*

P. helena. ♂: abdomen above brown, narrowly ringed with yellow, lighter in the middle, laterally and beneath entirely yellow; hindwing between the 1. radial and the 1. median truncate, except for the rather strong scalloping; the gold area correspondingly produced behind the 1. radial and at the 1. median; the upper angle of the spot placed before the 1. radial projecting more than the lower angle; behind the cell and the 2. median a long, narrow yellow triangle. The ♀ occurs in two principal forms, a light and a dark, which are connected by transitions; abdomen black-brown, at the sides a broad yellow stripe, the posterior ventral stripes partly yellow, or the whole underside yellow with black spots; hindwing usually without discal gold spot before the subcostal; the cell-spot small and irregular, or longer posteriorly than anteriorly. The most widely distributed „*Ornithoptera*"; it occurs in numerous subspecies from Hainan and North India to New Guinea. — **papuensis** *Wall.* (= melpomona *Rippon*, melpomena *id.*). Abdomen yellow beneath, in the ♀ paler than in the ♂ and spotted with black; cell-spot of the hindwing in ♂ and ♀ about of equal size, obliquely cut off, anteriorly reaching to the point of origin of the subcostal, sometimes somewhat more, sometimes somewhat less extended, the gold spot placed below the cell always extending nearly to the base. ♂ on the under surface of the forewing mostly without vein-stripes, but sometimes with a grey-white submarginal band composed of smears. The yellow area of the hindwing of the ♀ above very rarely grey-yellow. In ♂-ab. **irregularis** *Dannett*, founded on a single specimen, probably from New Guinea, the gold patches placed round the cell of the hindwing are so much reduced that the middle spots are scarcely a third as long at the veins as the black submarginal area is broad. The name ab. **carolus** *Fruhst.* is applied to specimens rarely occurring in both sexes in which the forewing is white above and beneath in the apex of the cell and at the veins on the disc; this white area is purer white in the ♀ than in the ♂ and extends almost to the hindmargin. Apart from such extreme individuals the ♀ occurs in two principal forms: ♀-f. **papuensis** *Wall.*, forewing at least above without stripes or only slightly lighter at the veins; this is the commonest form, to which also belongs ♀-ab. **biroi** *Horv. & Mocs.*, with yellow-brown instead of yellow area on the hindwing (discoloured?); in ♀-f. **papuana** *Oberth.* (= melpomona ♀ *Rippon*) the apex of the cell and the adjoining parts of the forewing above are grey-white. The butterfly occurs in the whole of New Guinea both in the plains and hills, but not in the higher mountains, and is very common in many places, e. g. Astrolabe Bay; it is also found on Salawatti. It is very singular that there is apparently no representative of these golden and black Aristolochia-Papilios on the Aru and Key Islands. — **hanno** *Fruhst.*, from Goram and the Matabela Islands, is smaller than *oblongomaculatus* from Ceram and Amboina. ♂ always without dark vein-stripes on the under surface of the forewing; hindwing before the subcostal always with a large golden spot, which basally, however, extends very little if at all beyond the point of origin of this vein, the cell-spot not so large as in *oblongomaculatus;* the cell rather strongly margined with black all round, the spot placed below the cell extending at least as far basad as the cell-spot. ♀: abdomen beneath at the base black, posteriorly grey-yellow with black spots; the central area of the hindwing grey-yellow as in *oblongomaculatus;* no discal spot before the 1. radial, the submarginal spots above and beneath small; no grey-yellow stripe at the submedian, or only a short one. Two forms: ♀-f. **lucina** *form. nov.* Cell of the forewing above only faintly edged with grey at the apex, the vein-stripes though distinct more or less shaded with black; ♀-f. **diana** *form. nov.* Apex of the cell and vein-stripes on the upper surface of the forewing grey-white. — **asartia** *Rothsch.* ♂: cell-spot of the hindwing extending nearly to the base, the subcostal spot either as large as in *oblongomaculatus* or smaller; on the underside the long spot placed below the cell reaching almost as far distally as the preceding golden area; cell more thinly edged with black than in *hanno*, the tips of the projections of the black marginal band covered with grey-yellow scales, the proximal portion of the last projection reduced to an isolated black dot (which is wanting in one of our three specimens). Ceram Laut, collected by H. Kühn in December 1898. — **oblongomaculatus** *Goeze* (= helena *Clerck* nec *Linné*, amphimedon *Cr.*, hellen *Godt.*), from Ceram, Saparoea and Amboina, is the largest subspecies of this species. ♂: cell-spot of the hindwing extending nearly to the base, the subcostal spot produced basad to beyond the point of origin of the subcostal. ♀: the central area of the hindwing above grey-yellow or cream-colour, a small discal spot before the 1. radial very rarely absent, the spot placed below the cell mostly large, *papuensis.* *irregularis.* *biroi.* *papuana.* *hanno.* *lucina.* *diana.* *asartia.* *oblongomaculatus.*

amaura. the black discal spots beneath more or less margined with grey; two forms: ♀-f. **amaura** *form. nov.*, apex of the cell of the forewing above only faintly edged with dark grey; ♀-f. **oblongomaculatus** *Goeze*, the apex of the cell broadly grey-white. Sometimes in the ♂ small, irregular black spots are sprinkled over the gold area. Ribbe found the butterfly in Ceram, „everywhere in the forest and on the coast where there are shrubby woods." Larva of *oblongomaculatus* similar to that of *haliphron*, grey-brown, with blackish lines on the back, two oblique bands laterally; on Aristolochia momandul. Pupa yellow-green, much shorter than that of *P. priamus*, the wing-cases project more strongly, the 2. and 3. pair of protuberances on the abdomen are much larger, and the 4. pair absent, also the last segments are more flattened above and laterally. Egg (according to Kubaly) small,
bouruensis. green, with thick shell. — **bouruensis** *Wall.* (10 b). ♂: the cell-spot and the subcostal spot of the hindwing mostly very much reduced, the latter usually placed at a distance from the point of origin of the subcostal, the cell-spot sometimes not larger than in the ♀ of the preceding subspecies, also the gold streak placed below the cell mostly small, above sometimes quite wanting. ♀: central area of the hindwing above and beneath deeper yel-
capnodia. low than in the previous subspecies; in the ♀-f. **capnodia** *form. nov.* the apex of the cell of the forewing on the upper-side is only slightly dark grey at the apex and the vein-stripes are effaced or indistinct; beneath, as in the prece-
argidia. ding subspecies, these stripes are grey-white and in one of our specimens very broad; in ♀-f. **argidia** *form. nov.* the apex of the cell of the forewing and the vein-stripes are grey-white also above, but the stripes placed at the
bandensis. 2. median and the submedian are short or diffuse. Buru, apparently common. — **bandensis** *Rothsch.* Smaller than *oblongomaculatus*, abdomen above deeper black-brown; hindwing somewhat more rounded, the cell-spot large, sinuate basally and therefore less obliquely truncate than in *oblongomaculatus*, the upper tooth of the 3. gold spot little if at all more produced than the lower one, on the contrary the teeth of the 5. and 6. spots placed at the 1. median vein long; the white fringe-spots are only just indicated. ♀: cell of the forewing above with rather sharp grey-white M-mark in the apex; the vein-stripes sharp and grey-white, but the subcostal spots beyond the fork of the 4. and 5. vein strongly shaded with black, the other stripes also less light distally and not extending so near the margin as in light-striped *oblongomaculatus;* the stripes of the 2. median and the submedian much darkened. Also beneath the apex of the cell is sharply surrounded with grey-white; central area of the hindwing above deeper yellow than in *oblongomaculatus*, but beneath quite as pale as in that subspecies; before the 1. radial always a discal spot, which often reaches to the subcostal; the spot placed below the cell large, the fringe-spots above and beneath very narrow. Only this one, comparatively constant ♀-form known. Great Banda,
thestius. collected by H. Kühn in November and December 1898. — **thestius** *Stgr.* (= leda *Stgr.* nec *Wall.*, celebensis *Rothsch.* [partim]). The smallest local form of this species. The ♂ very variable, forewing above at least with indications of vein-stripes, sometimes strongly striped with white, beneath always striped as far as the cell, and the latter at the median often margined with white down to the base. Veins of the
bernhardus. hindwing mostly very strongly black, the first discal spot and the cell-spot either very large: ♂-ab. **bernhardus** *Fruhst.*, or both more or less reduced: ♂-ab. **thestius** *Stgr.* In the ♀ on the upper surface of the forewing the edging of the apex of the cell and the vein-stripes distinct or indistinct, beneath very light and broad, the stripe placed before the 2. median reaching the cell, also the submedian stripes longer than in the forms from the Moluccas; central area of the hindwing yellow, the cell-spot occupies about half or $^2/_5$ of the cell; before the 1. radial a discal gold spot, the black discal spots large, confluent, the yellow spots between them very small, above often entirely absent; the marginal spots large, especially beneath. Saleyer.

In the following forms of *P. helena* the hindwing has a narrower black distal margin than in any
neoris. of the preceding subspecies. — **neoris** *Rothsch.* Abdomen above much paler than in *hephaestus*, yellowish brown, laterally and beneath grey, not yellow, only yellow towards the base in the ♂, the dorsal median spot of the ♂ scarcely lighter than the rest of the upperside, the black ventral spots of the ♀ small. ♂: forewing with extremely slight traces of vein-stripes; beneath the distal margin somewhat more incurved than even in *hephaestus;* hindwing as in that form, the marginal band as broad as in broad-margined *hephaestus*. ♀: forewing at all the veins, even the submedian, with broad grey-white stripes, which are even broader beneath than above, the stripes placed at the 2. median remote from the cell, the black basal area of the forewing rather sharply defined, the apical third of the cell grey-white, above with 2 black stripes shaded with white, beneath almost pure white; hindwing above as in *hephaestus*, somewhat less deeply scalloped, the white marginal spots larger, the black marginal band broader, the black abdominal margin rather strongly scaled with grey, especially at the anal angle; the black discal spots isolated as in many *hephaestus*, the 1. submarginal spot grey; no discal gold spot before the subcostal; the cell-spot cut off almost straight; beneath the central area yellowish grey, only in the middle more distinctly yellow. A pair from Binongka, Toekan Bessi Islands,
mopa. south-east of Celebes, taken by H. Kühn in December 1901. — **mopa** *Rothsch.* A transition form between *neoris* and *hephaestus*, from Buton, south-east of Celebes, only 1 ♀ known, captured by H. Kühn in December 1901. The vein-stripes and cell-pattern of the forewing as in strongly striped *hephaestus*-♀♀, but the black margin of the hindwing broader, the yellow area on the under surface anteriorly, posteriorly and proximally
neoris. as pale as in **neoris,** but a larger part of the area distinctly golden. Abdomen somewhat more distinctly yellow
hephaestus. than in **neoris,** the black ventral spots small. — **hephaestus** *Fldr.* (= leda *Wall.*) (13 a, b). A rather common

butterfly throughout Celebes in suitable localities, occurring both in low country and in the hills. Forewing long, above rarely with slight indications of vein-stripes, these stripes sometimes very distinct beneath; hindwing always with a large, long gold spot before the subcostal, which distally extends to the costa, the black marginal band broader than in the following subspecies and less deeply incised. ♀: forewing beneath with a broad white stripe at the submedian even when the wing has no other stripes; cell-spot of the hindwing obliquely truncate, anteriorly extending to the point of origin of the subcostal vein or even shorter; marginal band as in the ♂ comparatively broad at the veins; two principal forms: ♀-f. **lygaea** *form. nov.*, *lygaea.* forewing above without distinct vein-stripes; ♀-f. **lucinda** *form. nov.*, forewing above and beneath with grey- *lucinda.* white vein-stripes and the apex of the cell of the same colour. PIEPERS says that the insect also occurs on Saleyer, which probably rests on a confusion with *thestius Stgr.* — **propinquus** *Rothsch.* (14 a). Abdomen above *propinquus.* as dark as in *hephaestus.* ♂: forewing beneath with distinct or faint vein-streaks; gold spot long, reaching the costa distally, 4 black discal spots, the last so united with the marginal and abdominal band that no yellow submarginal spot is left, distal part of the gold spot placed below the cell about 1/3 as long as the proximal part. ♀: the vein stripes of the forewing and the apex of the cell grey-white also above; hindwing with gold discal spot before the subcostal, the black marginal band more deeply incised than in *helena;* only the white-striped form known. Sumbawa, apparently very rare; the varions collectors who have been on the island (DOHERTY, EVERETT, FRUHSTORFER, etc.) have only captured very few specimens. — **sagittatus** *Fruhst.* The ♂ *sagittatus.* not constantly different from *propinquus;* forewing rarely with vein-stripes, but these sometimes very distinct; the gold spot placed before the subcostal of the hindwing mostly narrow, sometimes very small, rarely absent, but sometimes as large as in *propinquus,* the yellow streak-spot placed below the cell longer than in that subspecies; most specimens with 2 black discal spots, often only the anal one present, sometimes 3 or 4, always a submarginal gold spot at the anal angle. ♀: hindwing without discal gold spot before the subcostal, commonly also the gold spot placed below this vein much reduced; the black discal spots always large, not very variable, at least the posterior ones united with the marginal band; two forms: ♀-f. **sciara** *form. nov.*, forewing above *sciara.* without distinct vein-stripes, and ♀-f. **nympha** *form. nov.*, forewing also above with strong vein-stripes and *nympha.* grey-white apex to the cell, the extent of the white in the cell variable. Lombok, rather common. — **nereides** *nereides.* *Fruhst.* ♂ very similar to that of the Javan form; hindwing with a row of black discal spots. In the ♀ the cell and disc more extended grey-white. Bawean. — **antileuca** *Rothsch.* Abdomen above as dark as in *antileuca.* *sagittatus,* not so distinctly lighter in the middle as in *helena* from Java. ♂: forewing above and beneath entirely without vein-stripes; hindwing similar to that of *helena,* without discal gold spot before the subcostal. ♀ above without vein-stripes and with the apex of the cell not margined with grey, beneath with quite indistinct traces of vein-stripes; hindwing with a discal and a submarginal gold spot before the 1. radial, both very small, the gold spot placed below the cell almost reaches the base; the black discal spots moderately large, the last 3 united with the marginal band, the cell-spot cut off in the prolongation ef the 1. radial. A pair from the Kangean Islands (PRILLWITZ), in the Tring Museum. — **helena** *L.* (= astenous *F.*, heliacon *F.*, *helena.* nymphalides *Swains.*) (11 c). ♂: forewing also above at least with traces of vein-stripes, these beneath mostly broad, sometimes reduced to faint submarginal patches, the upper ones often reaching the cell; the apex of the cell commonly grey-white, no white or yellowish streak behind the cell between the 2. median and the base; hindwing usually without gold spot before the subcostal, sometimes with one or two small spots or with a long narrow streak before that vein; on the disc 0—5 black spots. ♀: forewing above always at least with faint submarginal vein-stripes, these beneath always distinct and in the middle between cell and distal margin broader than the brown-black interspaces, the stripes placed at the 2. median vein not extending to the cell, usually also the preceding pair shortened; no stripe behind the cell between the 2. median and the base, sometimes the distal half of the wing almost entirely white-grey; the cell-spot of the hindwing very variable, sometimes only occupying 1/4 of the cell; no yellow discal spot before the subcostal; the black discal spots very variable, often large and joined together, and just as often small, but very rarely quite absent; we differentiate 2 forms: ♀-f. **penetia** *form. nov.*, forewing above without grey-white apex to the cell and without *penetia.* distinct, long grey-white vein-stripes and ♀-f. **pompeus** *Cr.*, forewing also above with grey-white apex to the *pompeus.* cell and grey-white vein-stripes; these cell-patches mostly longer than broad and produced anteriorly towards the base, not M-shaped. The specimens of both sexes in which the black discal spots are wanting on the hindwing are ab. **jupiter** *Oberth.*, whilst those with yellowish red hindwing are ab. **rutilans** *Oberth.* *jupiter.* *rutilans.* (= holzi *Pagenst.*). In ab. **pluto** *Fldr.* the yellow area of the hindwing is likewise yellowish red anteriorly, *pluto.* the vein-stripes of the forewing are indistinct above, but beneath as broad as in Javan specimens; the specimen (♀) is without indication of locality and probably does not come from Java, as it has on the under surface of the forewing behind the cell basally from the 2. median a strong white streak, which is commonly found in ♂ and ♀ from localities further west, but never seems to occur in Javan specimens. Java and South-West Sumatra. — **nereis** *Doh.* ♂: forewing above with distinct vein-stripes, which on the under surface *nereis.* are narrower than in *helena;* hindwing before the subcostal with long gold spot, which does not reach the costa; sometimes a complete row of black discal spots. ♀: apical third of the cell of the forewing and the sharply defined vein-stripes almost pure white, the stripes placed at the 2. median not reaching the cell; hindwing above pale yellow, beneath cream-coloured, the black discal spots large, joined together. Engano.

isara. — **isara** *Rothsch.* The ♂ not constantly differing from Sumatra specimens; vein-stripes of the forewing above usually indistinct, beneath always very distinct; the gold spot placed before the subcostal of the hindwing, as well as the one below the cell, always large. The ♀ approaches *nereis:* the apex of the cell of the forewing above white-grey at least to the 1. median, enclosing two black longitudinal spots, the vein-stripes as sharp as in Sumatran specimens, but the submedian stripes larger and purer white-grey, also a couple of thin stripes on the submedian fold; hindwing in one of the two ♀♀ before me with discal gold spot before the subcostal, in the other on the contrary with large, wedge-shaped yellow submarginal spot; beneath the yellow *typhaon.* area paler than in the Sumatra form, but deeper yellow than in *nereis.* Nias. — **typhaon** *Rothsch.* ♂: forewing above without vein-stripes, these beneath distinct or only very ill-defined, in the first case also a subbasal streak present below the cell; the gold spot placed before the subcostal always large, distally touching the costa. ♀: cell of the forewing above margined with white at the apex, the edging much broader anteriorly than posteriorly, much less M-shaped than in the Indian *cerberus,* the vein-stripes above and beneath mostly well developed, narrower than in *helena,* mostly a subbasal streak below the cell, the stripes placed at the discal and subcostal veins reaching the cell even when they are only weakly developed; the cell beneath with broad grey-white apical patch or the bordering narrow and posteriorly only rarely extending beyond the third radial, the black discal spots of the hindwing often large and joined together. The form in which *aplotia.* the upper surface of the forewing bears only weak vein-stripes I call ♀-f. **aplotia** *form. nov.*, and the form *phycia.* with strong vein-stripes and cell-spot ♀-f. **phycia** *form. nov.*, North-East Sumatra, in the plains and the foot-*heliconoides.* hills, the whole year through, but less common than *P. amphrisus ruficollis.* — **heliconoides** *Moore* (= heliaconoides *Wood-Mas. & Nicév.*). Smaller than *cerberus.* ♂: the gold spot placed before the subcostal always large, distally rather suddenly widened to the costa and here mostly enclosing a black spot, the tooth of the gold area placed before the 3. radial shorter than the one below this vein; the black marginal band beneath before the anal angle with short yellow longitudinal stripes on the black. ♀: forewing above almost pure black, or with very sharp, narrow, almost pure white vein-stripes, which do not extend so near to the margin as in *cerberus,* the stripe placed below the 2. median short or absent; the cell in striped specimens with sharp white M, beneath no white stripe below the cell basally to the 2. median, but in otherwise only weakly striped specimens a double stripe at the submedian; the black discal spots of the hindwing separated from one another, the 1. at most twice as large as the 2., the last spot of this row (placed below the 2. median) stands in or distally to the middle of the 2. median vein and at least beneath very little if at all proximally to the preceding black discal spot, the posterior teeth of the gold area mostly continued to the fringe-spots *rhyparia.* by yellow-grey scaling; two forms: ♀-f. **rhyparia** *form. nov.*, upper surface of the forewing almost pure black, *aphnea.* and ♀-f. **aphnea** *form. nov.*, with sharp white vein-stripes on the upper surface of the forewing. Andamans. *cerberus.* — No representative of this group of Papilios is yet known from the Nicobars. — **cerberus** *Fldr.* In North India and Burma this subspecies is much more variable than in Tonkin, Malacca and Borneo, which is probably connected with the fact that in those districts there is a pronounced cold, dry season (winter). The ♂ occurs in North India and Burma in two forms: ♂-f. **cerberus** *Fldr.*, forewing beneath below the cell with a white or yellowish stripe towards the base, the vein-stripes mostly distinct, though short, often present also above, *eumagos.* on the hindwing a large, long gold spot before the subcostal; in the 2. form: ♂-f. **eumagos** *form. nov.*, the forewing has no distinct vein-stripes or these are submarginal, and the subbasal stripe behind the cell is absent, the golden subcostal patch of the hindwing is reduced to a submarginal spot. With these two ♂-forms fly two principal forms of the ♀: a dark form, in which the vein-stripes are weak or almost entirely absent, ♀-f. *azelia* **azelia** *form. nov.*, and a form strongly striped with grey-white, ♀-f. **gypsothelia** *form. nov.*, in which the stripes *gypsothelia.* placed at the two median veins reach the cell, and the white margining of the apex of the cell extends nearly or quite to the point of origin of the 1. median; specimens which connect these two forms also frequently occur. In the Malay Peninsula and on Borneo as well as on the Natuna Islands, the ♂ has always a large, long golden subcostal patch on the hindwing, whether the forewing bears vein-stripes or not. The dark form of the ♀ from these countries is apparently not distinguishable from the before mentioned North Indian intergrades of the ♀, on the other hand in the striped form the white margining of the cell-apex does not extend basad beyond the 1. median and the stripes placed at the median veins do not usually reach the cell, commonly also the two stripes of the 3. radial are proximally effaced. A Borneo ♀ in the Tring Museum, taken by Wallace, has instead of the M-marking a short, broad grey-white apical patch in the cell of the forewing. A ♀ from Banguey in coll. Staudinger (Museum Berlin) has more gold on the hindwing than usual. Also in Tonkin, whence the Tring Museum has 2 ♂♂ and 3 ♀♀, the butterfly is apparently more constant than in North India and Burma; the ♂♂ have vein-stripes on the forewing and the golden subcostal patch of the hindwing is very large, but the black marginal band of the hindwing bears on the under surface before the anal angle only traces of yellow scaling, in distinction from *cerberus;* the ♀♀ are strongly striped with white and agree with the ♀-f. *gypsothelia* of *cerberus,* except that the teeth of the gold patch placed between the 1. and 2. median are not connected with the fringe-spot by yellow-grey scaling. In North India (Sikkim, Bhutan, Assam) and Burma *cerberus* is a common butterfly, occurring up to a height of 3000 ft. from the spring till the autumn; the light striped specimens appear mostly to come from hibernated pupae; in Borneo the insect is not common. — *spilotia.* **spilotia** *Rothsch.* ♂: the vein-stripes also above very distinct, especially those placed at the median veins,

beneath all very strongly developed, before the submedian a long, broad stripe, as well as weak stripes at the subcostals, the stripe placed behind the 2. median continued basad along the cell, as in *cerberus;* hindwing before the subcostal with a long gold patch, which does not reach the costal vein, a complete row of black discal spots (6 above, 7 beneath), the 2. the largest, 9 mm long, at the tip of the 3 posterior projections of the black marginal band somewhat black scaling on the gold area (recalling *aeacus*), the gold streak placed behind the cell prolonged beyond the middle of the 6. black discal spot. ♀: forewing above with very dark narrow vein-stripes, these strongly developed beneath, in the apex of the cell an M-mark; hindwing without discal gold spot before the subcostal, the black discal spots large, only at the 3. radial and 1. median very narrowly separated, the black spot behind the 2. median long, only 5 mm from the cell, beneath the yellow area very pale, distally and posteriorly whitish. 1 ♂, 2 ♀♀ from Hainan in the Tring Museum.

P. minos *Cr.* (= astenous *F.* partim) (9 a, b). The collar as well as the sides of the breast and of *minos.* the 1. abdominal segment red. ♂: abdomen grey-yellow, with black lateral spots; the 3. radial and the two median veins distinctly edged with whitish, these stripes continued to the cell and here united together; hindwing golden, the abdominal area as far as the cell and the broad marginal band black. ♀ on the forewing with very distinct vein-stripes, which extend to the cell and are here united, the distal half of the cell surrounded with white also on the inside; hindwing golden, the abdominal area black, and also a row of large discal spots, some of which rarely touch one another, and the broad marginal band (strongly convex between the veins), abdominal area grey in the centre and at the margin. Egg reddish. Larva dark brown, with blackish markings, the tubercles with pale red tips, the oblique lateral band and the whole dorsal tubercle of the 7. segment likewise pale red. Pupa usually light brown and dorsally golden; sometimes greenish and dorsally light yellow. South India, from the coast upwards to over 2000 m. In North Kanara common during the rainy season (from June onwards), also no rarity in other districts of the peninsula: Travancore, Cochin, Nilghiri Hills, Koonoor, etc. The butterfly has a slow flight, but flies commonly high above the trees, and often remains fluttering before flowers. The pupa when touched makes a distinct, somewhat hissing sound, which is probably caused by the friction of the abdominal segments against each other.

P. aeacus. ♂: abdomen above ringed with yellow; forewing narrow, semitransparent at the veins; hindwing golden, the last 3 projections of the black marginal band surrounded with black scaling placed on the golden area, sometimes a black discal spot behind the 2. median, rarely a second one also before this vein. ♀: abdomen above black, beneath margined with yellow, or yellow with black spots; hindwing with sharp white-grey vein-stripes, which extend to the cell; the cell inside margined with white-grey at least to the half, commonly almost the whole cell of this colour, only the base and 2 longitudinal streaks remaining black; hindwing with large black wedge-shaped spots and deeply incised marginal band, the anal third of the wing more or less strongly shaded with black. Distributed from the southern slopes of the Himalayas and West China to Malacca and Formosa; in many districts common from about 800 to 3500 ft. — **thomsoni** *Bates* *thomsoni.* (= malaiianus *Fruhst.*). ♂: small, the distal margin of the forewing strongly concave. ♀: cell of the forewing towards the base surrounded with white-grey scarcely to the 2. median, the bordering as well as the vein-stripes narrow; the black discal spots of the hindwing on the whole smaller than in Indian specimens, the wing anally less dusted with black. Malay Peninsula. — **aeacus** *Fldr.* (= rhadamanthus *Bdv.* partim, nec *aeacus.* *Lucas*) (vol. I, 1 a, b). ♂: larger, yet many specimens from the Shan States as small as *thomsoni;* the distal margin of the wing mostly less incurved, and the vein-stripes somewhat broader. ♀: the white-grey margining of the cell of the forewing as well as the vein-stripes broad, often the cell for the most part white-grey; in specimens from West China the abdomen beneath is on the whole more extended black than in those from India. North-West and North India, Burma including Tenasserim and the Shan States, and West China; from Siam proper, as well as from Assam, Tonkin, South China and Hainan, the butterfly is apparently not yet known; on the other hand it occurs in Formosa in a somewhat different form (*formosanus*). In North India, especially in the Mussorie district and Sikkim, the butterfly is very common in hot valleys. It sails slowly round flowering trees, but also visits flowering shrubs, and can sometimes be caught with the hand when it is hovering before a flower. — **formosanus** *Rothsch.* The vein-stripes of the forewing in ♂ and ♀ *formosanus.* narrower than in *aeacus,* especially in the ♀ strikingly thin. The abdomen beneath at the base with red hairs; in the ♀ the head before the antennae is red, also in the ♂ there are some red hairs here. The black discal spots of the hindwing of the ♀ are large and wedge-shaped, and the two black marginal spots placed before and behind the 1. median of the hindwing are not distally surrounded with yellow on the underside. South and Central Formosa, in the Tring Museum.

P. rhadamantus. Similar to the preceding species, but the 2. median of the hindwing branching off much more distally; the abdomen of the ♂ above entirely black; in the ♀ the forewing from the base to the point of origin of the 2. median brown-black, this area sharply defined, the double stripe placed at the 2. median short, the submedian double stripe at least above absent or merely indicated and the black distal spots of the hindwing so completely united with the marginal band that no yellow submarginal spots or only very small ones remain. Sometimes all the yellow is suppressed on the upper surface of the hindwing. Larva chocolate-brown, the tips of the fleshy spines red, on the 6. and 7. segments (not counting the head)

a reddish white lateral band as in the allied species. Pupa greenish yellow. Philippines, Palawan and Talaut Islands; three subspecies. — **rhadamantus** *Lucas* (= amphrisius *Lucas* nec *F.*, rhadamanthus *Bdv.* partim, nephereus *Gray*, basilanicus *Fruhst.*) (12 c) inhabits the Philippines and appears to be common on all the islands of the group. ♂: the black dusting on the anal part of the gold area of the hindwing usually only reaches half-way to the cell, sometimes it extends into the cell, but the underscales always remain yellow. The ♀ always with a large gold spot behind the cell of the hindwing, whilst the spot placed before the subcostal is always smaller than the patch between the two median veins and is often entirely absent. — **plateni** *Stgr.* (10 c). ♂: hindwing on the upperside from the anal angle at least nearly to the anterior margin of the cell entirely black, sometimes only one gold patch is left, beneath on the contrary the gold area in many specimens is almost as large as in the preceding subspecies, whilst in others it is more or less strongly reduced. In the ♀ the gold spot placed behind the cell of the hindwing is small or absent, rarely as large as in *rhadamantus*, the spot before the cell on the contrary is mostly larger than the one between the two median veins; beneath the golden area is more dusted with grey than in *rhadamantus*. Palawan. — **dohertyi** *Rippon* (= vordermani *Snell.*) (13 a, b). ♂ above on both wings black, sometimes anteriorly on the hindwing a vestige of the gold area present; beneath the hindwing has always a golden discal band; this, however, varies in width. ♀ paler than in the preceding forms, the gold area of the hindwing above much reduced, often suppressed altogether. Specimens of both sexes in which the vein-stripes of the forewing beneath are merged together are found together with normal specimens: ab. **fasciculatus** *Lathy.* Talaut Islands, probably especially on the principal island Talaut (= Talaur = Salibaboe); apparently not rare.

rhadamantus. *plateni.* *dohertyi.* *fasciculatus.*

P. magellanus *Fldr.* This magnificent species is widely distributed in the Philippines, but is much rarer than *P. rhadamantus*. It is known so far from the Babuyanes, Luzon, Polillo and Mindanao. Most probably it is also represented on Mindoro. Abdomen above and beneath grey-yellow, in the ♂ above laterally more or less blackened; the forewing with light vein-stripes extending to the cell; the hindwing golden, in the ♂ above and beneath with strong, brilliant opaline gloss, which is also indicated in the ♀, the distal margin of the ♂ narrowly black, in the ♀ merged together with the discal spots into a broad band, which bears a row of strongly curved yellow crescents. The vein-stripes of the forewing in the ♀ are rather variable in width and sometimes the cell of the forewing inside is margined with white-grey. According to Semper the ♂ when flying is one of the most gorgeous sights among the fauna of the Philippines, on account of the opalescent gloss. The butterfly apparently occurs all the year round and on the eastern islands of the group is no great rarity (but still always very rare in collections).

magellanus.

In the 3 following species the subcostal of the hindwing is more distally placed than in the preceding yellow species; the breast has very rarely a trace of red hairs on the underside and the genitalia are of another type than in all the other species.

P. miranda. Collar yellow or entirely black. ♂: abdomen yellow, above browned along the middle and the 1. segment black; forewing with blue shimmer and white or yellowish vein-stripes; hindwing golden, the black distal margin broad, measuring at the 2. median at least 5 mm and before this vein at least 10 mm. ♀; abdomen above black-brown like the forewing, beneath and laterally greenish yellow; forewing with sometimes weak vein-stripes, as in the ♂ only the posterior ones prolonged basad; the black discal spots of the hindwing very large and more or less strongly joined to the broad marginal band, the gold spots variable, often very much reduced. Borneo and Sumatra. — **miranda** *Btlr.* (14 b, c) is no rarity in the hilly country of North Borneo. Collar yellow, more rarely quite black; the vein-stripes of the forewing are submarginal, with the exception of the subcostal stripes, which often extend nearly or quite to the cell, no grey scaling inside the cell. Forewing of the ♂ above and beneath with rather strong blue sheen.*) — **neomiranda** *Fruhst.* (= zacheri *Suff.*). ♂: forewing less blue than in the Borneo form, the vein-stripes longer and yellower, the anterior ones extending to or into the cell. ♀: darker brown, the anterior vein-stripes of the forewing reaching to the cell, the hindwing more extended golden. In the mountains of Sumatra; 2 ♂♂ in the Tring Museum, 2 ♀♀ in coll. H. J. Adams (Enfield).

miranda. *neomiranda.*

P. andromache. A small species with red collar. ♂: forewing obtuse, on the underside with a band of large yellowish grey discal wedge-shaped patches; hindwing longest in the middle, the 2. and 3. projections of the marginal band produced at least as far as the 5.; abdomen above black-brown. ♀: abdomen black-brown, the margins of some at least of the segments beneath greenish yellow. Forewing with the exception of the broad marginal band and the costal margin grey or brownish grey; cell of the hindwing entirely golden, on the other hand the gold discal spots placed at the apex of the cell small, beneath the yellow spot behind the cell, and usually also the one before the cell, reaching to the base of the wing. Only known from the mountains of North Borneo; 2 subspecies. — **marapokensis** *Fruhst.* was taken by J. Waterstradt in considerable numbers on Mt. Marapok in the province of Dent in British North Borneo. The ♂ cannot be distinguished from that of the following form; however, the forewing of the ♀ is much more brown-grey than white-grey. — **andromache** *Stgr.* (13 c) comes from Kina Balu in British North Borneo. The forewing of the ♂ above

marapokensis. *andromache.*

*) This sheen, which only shows in certain lights, is unfortunately not perceptible in the figure.

sometimes shows traces of yellowish grey scaling. The forewing of the ♀ is white-grey and midway between the cell and the marginal band more or less extended brownish. The butterfly occurs up to a height of 1500 m.

P. amphrysus. ♂: abdomen yellow, the 1. segment above black, often the upperside also blackened laterally and at the tip; forewing with yellow or grey-yellow vein-stripes, the posterior ones submarginal, the anterior ones extending to the cell, the apex of the cell at least beneath with a grey-yellow spot; the black distal margin of the golden hindwing very narrow at the veins. ♀: abdomen above black-brown or grey-yellow; forewing with vein-stripes, of which the posterior ones are submarginal and are only sometimes prolonged to the cell when the latter is entirely filled in with white-grey, cell always with a white-grey apical spot, which is normally trapezoidal, but in Borneo is often very much enlarged and then not sharply cut off; the black discal spots of the hindwing always large. The butterfly is purely Malayan and occurs from Banguey in the north to Malacca. Sumatra, Java and the islands off the west coast of Sumatra in the south. The species is found in the lowlands and in the mountains and consists of a series of subspecies, of which three are mountain forms. The butterfly belongs to the commoner Lepidoptera of the large Sunda Islands and is more abundant there than *P. helena*. The egg is yellow. The full-grown larva is coffee-brown, the fleshy processes of the prothorax and the next 3 segments are thickened at the tip and curved posteriorly, whilst the processes of the other segments are inclined forwards. The yellow pupa makes a loud noise by rubbing the abdominal segments together when it is disturbed; the pupal stage lasts 26—29 days (Martin). Unfortunately it is not stated how the larva and pupa are distinguished from those of the allied species. The transparent yellow hindwings give the insect a gorgeous appearance when it circles high in the air in the sunshine. — **amphrysus** *Cr.* (= *amphrisius F.*) (14 a). ♂: vein-stripes and cell-spot of the forewing yellow, the stripes placed between the 2. and 3. radials proximally mostly broadly merged together; the black distal margin of the hindwing about 1½ mm broad at the tips of the veins; ♂-ab. **palabuana** *Fruhst.* has according to the author darker, almost reddish brown vein-stripes, our Palabuan ♂♂ do not show this, yet the vein-stripes in two worn specimens from there are paler and more dirty yellow. ♀: the yellow area of the hindwing above towards the base and the abdominal margin mostly very pale yellowish grey; abdomen beneath at the base usually blackened. Common on Java at lower elevations. Like the allied species *amphrysus* flies early in the morning and again towards evening, yet after heavy rain the butterfly is also to be found during the midday heat at flowers on open places covered with undergrowth, where it comes from the tree-tops in the edges of the neighbouring woods. — The mountains of Java are inhabited by a mountain form: **cuneifera** *Oberth.* (= ritsemae *Snell.*, cuneatus *Rippon*) (14 a, c), which flies at a height of about 1200 to nearly 2000 m. It occurs on Gedé and Ardjoena, but is especially common in the Chinchona plantations of the plateau of Pengalengan. ♂: abdomen above with an oval black spot on the 4. and the 5. segment; the hindwing has usually several diffuse obsolescent black discal wedge-spots, which are rarely all wanting; the vein-stripes of the forewing are thin, more grey than in *amphrysus* and the anterior ones only distinct at and near the cell. The ♀ not constantly distinguishable from *amphrysus*, the yellow area of the hindwing basally and abdominally less grey and especially beneath on the whole purer greenish yellow. — **vistara** *Fruhst.*, from the Batu Islands. ♂: vein-stripes of the forewing thinner and much less yellow than in *amphr. amphrysus*, the stripes placed at the 2. median above only indicated or absent; the projections of the black marginal band of the hindwing longer than in *amphrysus*. ♀: vein-stripes of the forewing somewhat broader than in *amphrysus*, especially the submarginal ones, the cell-spot somewhat larger, anteriorly almost as long as it is broad; marginal band of the hindwing broad, the yellow submarginal spots consequently further removed from the margin than in *amphrysus*, the central area above and beneath yellow, the yellow spot placed before the subcostal larger than the 4. spot, the 5. and 6. spots deeply incised, the respective black discal patches very long; abdomen beneath not blackened at the base. 2 ♂♂ and 1 ♀ in the Tring Museum, a few specimens also in other collections. — **niasicus** *Fruhst.* ♂ quite similar to the *vistara*-♂, but the vein-stripes of the forewing and the cell-spot somewhat more yellowish; on the under surface the cell has at the apex a large anterior and a small linear posterior spot, which is also the case in *vistara* and the next subspecies. The ♀ likewise as *vistara*, the cell-spot of the forewing posteriorly shorter, consequently strongly trapezoidal; the discal yellow spot placed before the subcostal of the hindwing is small, and the 2. yellow discal spot and also the grey-yellow submarginal spots are on the whole smaller than in *vistara*. Nias. — **sumatranus** *Hagen* is the mountain form from Sumatra. Similar to *cuneifera*. In the ♂ the vein-stripes of the forewing still more reduced, and the abdomen above without black central spots; the black discal spots of the hindwing only partly indicated, often all absent. The ♀ is distinguished from all the other *amphrysus*-forms especially by the gold area of the hindwing being cut off almost straight at the point of origin of the subcostal vein; the abdomen beneath blackened at the base as in *cuneifera*. — A further form with black discal spots on the hindwing of the ♂ is **tantalus** *Ehrm.*, described from a ♂ which is said to have been found by Waterstradt in North Borneo (— the author says „in the German possessions in North Borneo, . . Kala Bula Mountain"). The specimen differs from *cuneifera* according to the author by the absence of the red collar and by stronger yellowish vein-stripes. We would point out, however, that in *cuneifera* (= ritsemae) the collar is also sometimes entirely black and the vein-stripes vary. Did the specimen really come from North Borneo? — **ruficollis** *Btlr.* ♂: the vein-stripes of the forewing and the black distal margin of the

amphrysus. *palabuana.* *cuneifera.* *vistara.* *niasicus.* *sumatranus.* *tantalus.* *ruficollis.*

hindwing thinner than in *amphrysus*, the cell of the forewing beneath with a larger anterior and a linear posterior spot as in *vistara* and *niasicus;* the harpe of the anal clasper as in these two forms with a proximal tooth, which is only indicated in Javan specimens of *amphrysus*. In the ♀ the white-grey cell-spot extends to the point of origin of the 2. subcostal, the vein-stripes are narrower than in *amphr. amphrysus;* the yellow submarginal spots of the hindwing are placed nearer to the margin than in *niasicus* and *vistara* and in specimens from Malacca are rather frequently, in those from Sumatra rarely, joined together. We have found no characteristic by which the specimens from Malacca and Sumatra can be distinguished from one another. It is true that in general the ♂♂ from Malacca are small and the black discal spots of the hindwing of the ♀ in a large percentage of specimens are partly separated from one another and the anterior ones rounded, but the same characters likewise occur in Sumatra although rarely, so that it is so far impossible without indication of locality to say with certainty of any specimen whether it comes from Sumatra or Malacca. It is quite otherwise with the specimens from Borneo. In Sumatra, where *ruficollis* occurs in the plain and on the spurs of the mountains, it is commoner than the local form of *helena*. It flies all the year round, according to HAGEN most commonly in March, and is especially fond of visiting the flowers of Poinciana pulcherrima.

flavicollis. — **flavicollis** *Druce.* Whilst the preceding subspecies are comparatively constant, the species is very variable in Borneo, and there are distinguishing marks which are not found elsewhere, so that at least 4/5 of the specimens can be recognised as coming from Borneo. The collar is commonly yellow, which unfortunately has procured for the subspecies a name which is only suitable for a part of the individuals. ♂: abdomen above mostly with distinct brown central spots; cell of the forewing above often entirely without yellow scaling, the yellow spot sometimes found as in *ruficollis*, but often much enlarged anteriorly, beneath the anterior cell-spot is often so extended that half the cell is yellow, but even in this case the small linear posterior spot remains separate. ♀ occurring in two forms, a dark and a light, connected by transitions. The dark form, apart from the yellow collar which rarely occurs in this form, is very similar to the *ruficollis*-♀, but the cell-

actinotia. spot of the forewing is anteriorly mostly somewhat larger: ♀-f. **actinotia** *form. nov.* The light form, ♀-f.

olympia. **olympia** *Honr.*, has mostly a yellow collar, the cell of the forewing is entirely or for the most part white-grey, the vein-stripes are broad and long and those of the two median veins likewise extend to the cell, the black discal spots of the hindwing mostly and the gold spot placed before the subcostal always very large.

gardineri. FRUHSTORFER has introduced the following additional diesgnations according to the colouring of the collar:

bruneicollis. ♂-ab. **gardineri,** collar red, ♀-ab. **bruneicollis** (!) (= birmeicollis *Fruhst.*), collar brownish, and ♂♀-ab. **nigri-**

nigricollis. **collis,** collar black. *P. amphrysus flavicollis* is known from North and South Borneo as well as Banguey; the light ♀♀ possibly occur only in the north. The butterfly is common in the lowlands as well as the mountains of North Borneo and much more numerous than any of the allied species. Possibly a form of *amphrysus* also occurs on Palawan.

Nox-Group.

Entirely without tails, or the tail short and pointed, not spatulate. Hindwing of the ♂ with very broad, rolled-up abdominal fold, in which there is always a strongly developed scent-organ; the anal claspers normal, with short tooth at the tip as in the preceding group.

The species fall into two natural subgroups:

1. Scent-fold of the ♂ (when fully expanded) without long hairs at the edge; *semperi*, *dixoni*, *kuehni*, *priapus*, *sycorax*, *hageni* and *aidoneus*.
2. Scent-fold of the ♂ with long hairs at the edge: *varuna*, *zaleucus* and *nox*.

P. semperi. Body for the most part red. Anal claspers of the ♂ red with black ventral spot; the abdominal fold of the hindwing very large, with yellowish grey scaling, except at the base; upper surface of both wings in the ♂ pure velvety black, in the ♀ slightly lighter, the hindwing above with the markings of the underside only indicated or distinct, but whitish; in one form the forewing of the ♀ with large white spots; beneath the hindwing with 2 rows of red spots, the anterior spots of the discal row often absent. The butterfly, concerning whose habits practically nothing is known, is found only on the Philippines (including Palawan), where it apparently occurs on all the islands. It flies all the year round, but nevertheless is only

melanotus. taken singly. — **melanotus** *Stgr.* (18 a) is the most primitive form as regards the colouring of the body. It flies on Palawan. The thorax and abdomen are black above. In the ♀ the hindwing has only slight indications of markings above. So far as we know, only 2 ♂♂ (Museum Tring) and 1 ♀ (coll. STAUDINGER) are known. Palawan is thickly wooded and only accessible in a few places; collecting is also rendered much more

albofasciata. difficult to the traveller by the hostile attitude of the inhabitants. — **albofasciata** *Semp.* Thorax and abdomen red also above, in the ♀ pale. The ♂♂ of this and all the following forms do not appear to be distinguishable, whilst the ♀♀ exhibit striking differences. ♀: forewing with a row of very large white patches; hindwing with the markings of the under surface sharply developed above also, but the discal spots white, the

semperi. submarginal ones reddish white, shaded with black. Mindoro and (according to SEMPER) Panay. — **semperi** *Fldr.* (= erythrosoma *Reak.*) (17 b, c). ♂ as the preceding. ♀: forewing black, slightly paler on disc;

hindwing above black, with grey-black discal and submarginal spots. Luzon and Polillo. — **baglantis** *Rothsch.* ♂ as the preceding. ♀: hindwing above with sharply expressed reddish white markings, which however are much smaller than the red markings on the under surface; the anterior spots of the discal row are wanting; distal margin between tail and anal angle not edged with grey. Negros. — **supernotatus** *Rothsch.* ♂ and ♀ as the preceding, but the hindwing of the ♀ from the 2. radial edged with dirty reddish white. Samar and Bohol. — **aphthonia** *Rothsch.* ♂ as the preceding. ♀: the markings of the upperside of the hindwing much larger than in the preceding forms, almost as large as beneath, the anterior spots of the discal row present above and beneath; the distal margin posteriorly sometimes grey. On Mindanao and the small neighbouring islands. *baglantis. supernotatus aphthonia.*

P. dixoni *Gr.-Sm.* Similar to *P. kuehni.* Body and wings black-brown, the tip of the abdomen and a lateral spot at its base red. The middle of the wings much lighter; hindwing beneath with 4 crescents far away from the margin and a narrow straight red band, placed halfway between the crescents and the cell and extending from the 2. radial to somewhat beyond the 2. median; these spots weakly indicated above. — Buwool, North Celebes, 1 ♀ in coll. H. Grose-Smith. *dixoni.*

P. kuehni. Body black, a lateral spot on the prothorax, another at the base of the abdomen and the tip of the abdomen red. ♂ above almost pure black, the fold of the hindwing white inside. ♀ black-brown, the middle of the forewing much lighter; hindwing beneath in both sexes with large band-like red patches on the disc. East and North Celebes. — In **kuehni** *Honr.* the hindwing of the ♂ above is only very little paler in the middle than at the base and the distal margin. Tombugu, East Celebes. — In **mesolamprus** *Rothsch.*, from Toli Toli, North Celebes, of which we only know 1 ♀, the upper surface of the hindwing is broadly reddish grey distally to the cell. *kuehni. mesolamprus.*

P. priapus. Head, collar and sides of the breast yellowish white, abdomen beneath more or less extended white-yellow. Hindwing with broad yellowish white band, in which a row of black spots is placed; scent-fold of the ♂ white, edged with pale salmon-colour, towards the base black. In two subspecies on Java. The butterfly occurs in the highlands up to about 6000 ft. and is especially common in the Cinchona plantations of the table-land of Pengalengan, where Fruhstorfer found large numbers feeding at the flowers of Lantana. — In East Java, on the Arjoena, occurs **dilutus** *Fruhst.* The band of the hindwing is above more or less distinctly shaded with black and the whole upper surface of the ♀ is very pale. — The West Javan subspecies is **priapus** *Bdv.* (17 a). In this the abdomen is more extended yellow and white and the band of the hindwing above is less shaded with black, also the basal half of the hindwing is almost as black as the distal margin. *dilutus. priapus.*

P. sycorax *Gr.-Sm.* (= egertoni *Dist.*) (17 a, b). Head and collar white; abdomen above bluish grey with a row of black dots at each side, beneath yellow. Upper surface of the ♂ velvety black, of the ♀ much paler and more metallic; hindwing from near the apex of the cell to the black marginal band blue-grey, with a row of black discal spots; beneath this area is much lighter and extends to the margin, the posterior black marginal spots being separated from one another and from the margin. — West and East Sumatra and Malay Peninsula, in hilly country. The butterfly flies high and quickly, and is especially often taken at flowering trees in the woods. *sycorax.*

P. hageni *Rogenh.* (17 a). Similar to the preceding species. Abdomen above black, beneath red and black. Forewing of the ♀ very pale black-brown, the light stripes semitransparent. Hindwing in both sexes with large white discal area which encloses black discal spots, the cell broader than in *sycorax.* — Confined to Sumatra, where it is found only on the high plateau and like *sycorax* occurs all the year round. Hagen found it feeding at the flowers of Pavetta. Martin's collectors gave to these two butterflies the distinguishing name of Kapala Putih, White Head. *hageni.*

P. aidoneus *Dbl.* (= erioleuca *Oberth.*) (17 b, c). Head red, the long hairs often almost all black; the sides of the breast and abdomen red, and the sides of the latter mostly white-red. Wings blue-black, in the ♀ often brownish, the forewing lighter, with the usual black stripes at the veins and folds. Scent-fold of the ♂ as in the preceding species with white area, posteriorly edged with pale salmon-colour. — North-West India, Sikkim, Bhutan, Khassia Hills (very rare), Burma, Shan States, Tonkin and Hainan; in Sikkim not rare up to about 5000 ft. from April to November; according to Manders the butterfly flies by preference in the deep shadow of forest-trees which overhang rivers. Its flight is slow and graceful. *aidoneus.*

P. varuna. Very similar to *P. aidoneus.* The forewing of the ♂ beneath from the base to the 2. median or the apex of the cell bluish black; scent-fold black-brown, with a small white-grey or grey spot on the underside and long fringes. ♀: forewing before the hindmargin much lighter, usually with a large white area with indistinct margins; hindwing above almost uniformly blue-black, not brownish, above and beneath more strongly metallic blue than in *aidoneus.* Sikkim, Assam, Burma, Tonkin, Tenasserim and Malay Peninsula. The insect is commoner than *P. aidoneus* and in Sikkim is found up to 7000 ft. In North India it

flies from March to December, whilst in the more southern districts, which have no winter, it occurs all the year round. — **astorion** *Westw.* (♀ = chara *Westw.*) (19 a). ♂: forewing without white stripes on the under surface before the distal margin. ♀: the light area of the forewing on the upper surface almost pure white (spring specimens?) or rather strongly shaded with black-blue (summer specimens?). Sikkim to Tenasserim and Tonkin. Sometimes the hindwing of the ♀ has grey discal lunules, which are specially distinct beneath. — **varuna** *White*, from Penang and the Malay Peninsula, has in the ♂ white stripes before the distal margin on the underside of the forewing; sometimes the posterior stripes are also indicated above. In the ♀ the light part of the forewing above and beneath and the vein-stripes beneath (especially at the end of the cell) are purer white than in *astorion*.

astorion. *varuna.*

P. zaleucus *Hew.* (17 c). This species has a rather limited distribution; it occurs in Burma (including Upper Tenasserim), the Shan States and Tonkin. Head, sides of the breast and underside of the abdomen red, the last as in the allied species with black markings. Wings of the ♂ blue-black; hindwing before the distal margin with 3 white patches, which sometimes enclose small black spots. ♀ much paler than the ♂; hindwing with large white discal area, which usually extends from the 1. radial to the hindmargin and is dentate at the veins.

zaleucus.

P. nox. A purely Malayan butterfly, which is known from the 3 large Sunda Islands Borneo, Sumatra and Java, the Malay Peninsula, and also from Nias and Bali. In Borneo and Sumatra both sexes occur in 2 forms, which have hitherto been regarded as specifically different. Head and prothorax with the exception of the upperside red, and also the sides of the breast and the tip of the abdomen, the latter in the ♂ often without red spot. Wings of the ♂ black, above mostly with blue gloss, the veins of the forewing and sometimes also of the hindwing distally striped with grey on the under surface; the scent-scales in the fold of the hindwing light grey, somewhat yellowish. ♀ brown, with or without bluish metallic gloss; either only the forewing or both wings with yellowish grey vein-stripes. Larva marbled with black and brown, the tubercles pale red, on the 6. and 7. segments a white belt, the tubercles in which are also white. Pupa: margin of the head dentate; lateral lobes of the thorax with three teeth, the lobes of the abdomen produced into a point, also the 7. and 8. abdominal segments above with a narrow pointed process at each side, the 5.—8. segments with a small pointed hump beneath at the sides. In the lowlands and hills. The butterfly is a true forest species, which according to HAGEN is fond of visiting the flower-umbels of a species of Pavetta which often blooms in the midst of the darkest primeval forests. MARTIN sometimes found the ♂♂ at the edges of woods on the sweet-smelling, Veronica-like blue flowers of a small tree. The flight is slow, but so irregular that the butterfly cannot be caught in the undergrowth. — **noctis** *Hew.* (18 c), from North Borneo, is distinctly dimorphic especially in the ♀. ♂: wings mostly with rather strong blue gloss, the distal margin of the forewing usually convex before the middle, the apex therefore very obtuse, beneath the wing bears in the apical third yellowish grey vein-stripes, which are sometimes indicated also above. This form is f. **noctula** *Westw.* (18 b). Its corresponding ♀-form is that described as **strix** *Westw.*, in which the veins of the forewing (except in the basal third of the wing) and the distal third of the veins of the hindwing are striped with yellowish grey. The ♂ of the second form is less blue above and the forewing has also beneath no yellowish grey vein-stripes. Such specimens have hitherto been regarded as the true ♂♂ of *noctis Hew.* The ♀ placed with it, described by HEWITSON as *noctis*, is striped with yellowish grey in the apical third of the forewing, and the stripes of the hindwing are merged together into a broad marginal band, which encloses one or two rows of black spots. Some specimens of the ♀ of f. *noctula* approximate to the ♀ of *noctis*. — In South Borneo flies **banjermasinus** *Fruhst.* Forewing of the ♂ narrower than in most *noctis*-♂♂, without yellowish grey vein-stripes. ♀: forewing in the apical third with white vein-stripes and with blue gloss before the hinder angle; hindwing above blue, above and beneath at most with slight indications of grey vein-stripes. — **erebus** *Wall.* (18 c), from the Malay Peninsula and Penang, agrees very nearly with *banjermasinus*, but the ♀ appears to be always different, though only a little. The subcostal veins of the forewing of the ♀ and the 1. and 2. radials are broadly striped with white, beneath the 3. radial and 1. median are also accompanied by white stripes; the upper surface has usually some blue gloss before the hindmargin, but less than in *banjermasinus;* the hindwing is above blue, distally black between the veins, beneath the veins are mostly very distinctly striped with grey before the margin, but sometimes the stripes are only indicated; the fringes of both wings white. — The ♂ of **henricus** *Fruhst.* (= erebus *auct. pt.*), from North-East Sumatra, resembles the ♂ of *erebus*, except that the forewing is on the whole somewhat more blue; sometimes distinct grey vein-stripes are present on the underside of the forewing. The ♀ occurs in two forms connected by transitions, in both the fringes of the wings are usually darker than in *erebus*. One form resembles the *erebus*-♀: forewing above only striped with white between cell and apex, the stripes placed at the 1. and 2. radials do not reach the cell, sometimes all the stripes are remote from the cell, the other veins are more or less blue; the hindwing strongly blue, the black marginal areas smaller than in *erebus*, the veins above without white-grey stripes at the distal margin, these sometimes present beneath: ♀-f. **glenia** *form. nov.* The second form, ♀-f. **henricus** *Fruhst.*, is less blue, sometimes almost without blue gloss, the vein-stripes of the forewing are thinner, those placed at the upper radials reach the cell and the two median veins are also accompanied by more

noctis. *noctula.* *strix.* *banjermasinus.* *erebus.* *henricus.* *glenia.*

or less distinct grey stripes; hindwing above and beneath with white-grey vein-stripes at the distal margin. The two forms occur together; of the first we also possess a series from the neighbourhood of Siboga and Padang Sidempoean. — In South-West Sumatra, in the district of Padang and probably further to the south, occurs **solokanus** *Fruhst.* The ♂ is much less vivid blue than *henricus*. The forewing of the ♀ is more brown-black than in *henricus* and bears very narrow vein-stripes, above only at times somewhat whitish; the hindwing is moderately blue and has beneath before the distal margin grey stripes, which are sometimes indicated above also. — **petronius** *Fruhst.*, from Nias. ♂ similar to the *solokanus*-♂, but the black-brown stripes in the apical half of the underside of the forewing are broader, the black stripes placed between the veins are distally quite narrow. ♀ very pale, the grey stripes placed at the subcostals on the forewing very broad, the others narrower, beneath almost the whole cell grey; hindwing before the distal margin with grey stripes, which are mostly also distinct above. — **nox** *Swains.* (= neesius *Zink.*, ♀ = memercus *Godt.*) (18 b). ♂ black, with slight blue gloss, above the apical third and beneath about half of the forewing striped with brown; apex of the abdomen usually with distinct red spot. ♀ brown, forewing with light stripes between cell and apex. East and West Java. — **nyx** *Nicév.* flies on Bali; only 2 ♀♀ known (one in coll. Elwes; the other in coll. Nicéville, which is now in the Museum at Calcutta). The light stripes of the forewing between cell and apex even broader than in the ♀ of *nox*, often almost merged together.

solokanus. *petronius.* *nox.* *nyx.*

Latreillei-Group.

Hindwing elongated, with spatulate tail. Scent-fold of the ♂ and the scent-wool in it strongly developed; the anal claspers normal, without distinct tooth at the tip.

Whilst the preceding group is predominantly Malayan, the species of the *latreillei*-group only occur on the continent and the Chinese and Japanese islands; a single species (*philoxenus*) is said to have reached southwards to the Malay Peninsula.

P. latreillei. Head, prothorax, sides of the breast, and abdomen red, the underside of the latter red with black spots. Wings blackish brown, above and beneath pale. Hindwing with broad white discal band; 4, more rarely 5, submarginal spots, the posterior 3 red, the others more or less white, a spot in the tip of the tail red. Scent-wool of the ♂ white. North-West India, North India, Upper Burma and Shan States, from March to August; flies high over the tops of the trees in the thickest forest, but is sometimes taken resting on the forest-paths. — **latreillei** *Don.* (= minereus *Gray*) (19 b) occurs in North-West India (especially common in Mussorie), Nepal and Sikkim at a height of 7—9000 ft. The discal patch placed between the 3. radial and 1. median of the hindwing larger than the other patches. — **polla** *Nicév.* is found in the Shan States and Upper Burma at elevations of 3500 to 5000 ft. The discal patch placed between the 2. and 3. radials of the hindwing is larger than the others.

latreillei. *polla.*

P. adamsoni *Grose-Smith* (= mineroides *Elw. & Nicév.*) (19 c). Very suggestive of *P. aristolochiae.* Smaller than *P. latreillei;* the tail without red spot, the hindwing from the costa to the 1. radial much broader, the white discal band in the ♂ narrower; very commonly the submarginal spot placed before the 2. radial is connected with the corresponding discal spot. The ♀ much paler than the ♂. — Shan States and Tenasserim; January to March, rare.

adamsoni.

P. crassipes *Oberth.* (18 a). Forewing less triangular than in *latreillei;* hindwing in contour much like *latreillei,* without white discal band, and above without distinct submarginal and marginal spots, the spot at the tip of the short, broad tail small; beneath the red spots all large, inclusive of the tail-spot there are 6 present. — Tonkin and Shan States, at elevations of 1000 and 2500 ft.; only a few specimens known.

crassipes.

P. nevilli *Wood-Mas.* (= chentsong *Oberth.*) (vol. I, 1 c). The sexes almost alike. Hindwing proximally broader than in *P. latreillei* and the marginal teeth placed before and behind the tail less produced; tail without spot; two large white, sometimes slightly reddish spots between the subcostal and the 2. radial, the 2. spot reaching almost or quite to the cell, on the upper surface the 1. spot is sometimes very small or entirely absent, between the 2. radial and the 3. median 3 red or reddish submarginal lunules, which are larger beneath than above. Scent-wool yellowish white. — A very common species in West China, which also occurs in Cachar (Assam).

nevilli.

P. philoxenus. An individually and geographically variable butterfly, which is distributed from West China, Kashmir and North-West India to Annam and Tonkin, and also occurs on Formosa; it is not yet known from East and South China; a specimen in the Tring Museum is said to be from Taiping in Perak, which seems to us very questionable. Body as in the preceding species red and black; hindwing *latreillei*-like in contour, but broader, with 3 submarginal spots between the 2. radial and the 2. median and a double spot in the tail, as well as a sometimes very small admarginal spot at the end of the 1. median red, before the

2. radial mostly a large white spot, which is formed by the union of a discal and a submarginal spot, this patch sometimes constricted, in the Chinese subspecies usually only the submarginal spot present; behind this patch very often a second smaller one, very rarely a spot before the 2. radial; commonly the red anal spot in the ♀, especially on the under surface, prolonged in band-shape to the apex of the cell. Scent-wool of the ♂ grey-black; anal hook of the ♂ above with a second, short hook, the harpe feebly dentate. Larva purple-brown, with black spots, head and legs shiny black, the protuberances red at the tip, the 6. and 7. segment each with a short, oblique lateral band; found on Nepenthes. Pupa insufficiently described, reddish ocre-colour; makes a squeaking sound when touched. The butterfly is in places very common; in North India it is found in wooded districts at elevations of 1000 to 8000 ft. all through the summer. — The form occurring in China and North Cashmir is *lama Oberth.* (vol. I, pl. 2 a), whose wings, especially in the ♀, are paler than in the other subspecies; the folds of the cell on the underside of the hindwing stand out prominently. — *philoxenus.* **philoxenus** *Gray* (= letincius *Fruhst.*) (19 a). South Cashmir, North-West India and Nepal. The abdomen is beneath as black as in *lama*, also the hairs on the frons are much mixed with black, especially in the ♂. The hindwing has always before the 2. radial a large, undivided white spot, behind which at least beneath is placed a second, small spot. — In Sikkim, Assam, Burma, North Siam, Assam and Tonkin (also doubtfully in Malacca) occurs *polyeuctes.* **polyeuctes** *Dbl.* (= hostilius *Fruhst.*), which is among the commonest Papilios of this region. The frons and the underside of the abdomen less black than in the preceding subspecies; the under surface of the hindwing darker; the second white spot of the hindwing is wanting on the upperside in many ♂♂, but appears to be always present beneath; in one of our ♂♂ almost all the spots are very strongly blackened above. — *termessus.* **termessus** *Fruhst.* The specimens from Formosa are broad-winged and have rather large red spots on the hindwing; but the differences are not constant.

P. dasarada. Body beneath more woolly than in *P. philoxenus.* commonly at the sides of the abdomen pale red instead of vivid red. The anal hook of the ♂ simple; the harpe more strongly dentate than in *P. philoxenus,* distinctly different in the 4 geographical forms. Hindwing narrow, the cell narrower than in *philoxenus,* a large white spot before the 2. radial as in *philoxenus,* many specimens with a small spot before this patch, rarely also a spot behind it (in *philoxenus* the smaller spot is placed behind the larger), the submarginal spot placed before the tail white or whitish, in the ♀ often a complete macular band on the disc. Distributed from North-West India to the Shan States, Tonkin and Hainan; not quite so common as *philoxenus,* with which *dasarada* occurs at the same time in the same places. The butterfly is a forest species, which is usually taken at open spaces in the woods and at flowering trees, round which the butterfly sails with a slow, graceful flight. It has a very strong, offensive smell. The earlier stages are not known. Unfortunately this is the case with numerous common North Indian species. — *ravana.* **ravana** *Moore* (19 c); vol. I, 1 b) is the form from North-West India and Nepal. The hindwing beneath in the basal half is almost as pale as the forewing; the spot placed before the large white patch is very rarely wanting. — *dasarada.* **dasarada** *Moore* (19 b). The underside of the hindwing much darker than the forewing; the spot placed before the large patch is very commonly absent on both sides. In a ♂ from Sikkim in the Tring collection all the spots are strongly shaded with black and the spot at the tip of the tail is absent. The Tring Museum also possesses a similar melanotic specimen of *ravana.* Sikkim, Bhutan and Assam, common; very variable in size. — *barata.* **barata** *Rothsch.* has somewhat narrower wings than *dasarada* and the under surface of the hindwing is paler from the costal margin to the cell; the spot placed before the large patch is always (?) absent above and mostly beneath. The harpe of the ♂ has numerous teeth and is bent just behind the proximal process; in *dasarada* the harpe is straight and the teeth are large; in *ravana* it is slightly widened distally to the basal process and the teeth are smaller than in *dasarada,* also the basal process is commonly short and broad. Shan States and Tenasserim; Tonkin. — *melanurus.* **melanurus** *Rothsch.* All the spots of the hindwing small, above shaded with black, no spot in the tail and none at the end of the 1. median; under surface of the hindwing black. Hainan, 3 ♂♂ in the Tring Museum, taken in May.

P. daemonius. Head and sides of the breast and abdomen red, strongly mixed with black. ♂ above brownish black, beneath pale brown, the distal margin of the hindwing above and beneath black, with pale red submarginal spots. The ♀ above very pale grey-brown, beneath grey-brown, the distal margin black. The hindwing in ♂ and ♀ much more shortly lobed than in *plutonius,* the cell much broader and more rounded. The genitalia quite different from those of the similarly coloured species. The scent-wool of the ♂ white. West China and Yunnan. — *yunnana.* *daemonius Alph.* (= fatuus *Rothsch.*) flies in West China (vol. I, p. 9). — **yunnana** *Oberth.,* from Topintze in Yunnan, has paler submarginal spots than *daemonius.*

plutonius. **P. plutonius.** Head, collar, sides of the breast and abdomen as well as the black-spotted underside of the latter red mixed with black hairs. Hindwing before and behind the tail very strongly lobed, above 4 or 5 red or reddish submarginal spots and on the under surface 6 or 7 spots. Ground-colour of both wings above in the ♂ brownish black, in the ♀ blackish brown, the distal margin of the hindwing black; beneath both sexes blackish brown, the hindwing almost as pale as the forewing. Scent-wool of the ♂ black-brown. A species of the highlands of West China and of the eastern Himalayas. — In West China flies *plutonius Oberth.* (vol. I, 2 c). — The form which is known in a few specimens from the higher elevations of Sikkim

and Bhutan is **pembertoni** *Moore*. Paler than *plutonius*, the submarginal spots of the hindwing larger and very pale reddish. *pembertoni.*

P. mencius *Fldr.* (vol. I, 2 b) flies in Central and South-East China. Head, collar, sides of the breast and abdomen and the underside of the latter red mixed with black. The wings in both sexes brown-black, the forewing paler than the hindwing and the ♀ somewhat paler than the ♂. The hindwing is mostly shorter in spring specimens than in summer ones. Scent-fold of the ♂ shorter than in *P. alcinous*, the wool whitish grey. The harpe of the ♂ with 2 proximal processes. The butterfly is common. *mencius.*

P. impediens *Rothsch.* (vol. I, 3 a) resembles the preceding species. In the ♂ the wings are darker, the hindwing is narrower and proportionately more strongly widened before the tail (recalling *P. latreillei*), the scent-fold is shorter and the wool contained in it somewhat darker; the harpe is quite different: it is dentate and terminates distally in a semicircular fold, curved upwards. The ♀ according to Oberthür is greyish ochre-colour. — West China, only a few specimens known. The species doubtless occurs also in South-Eastern China, as the following species from Formosa is a very near ally of *impediens*. *impediens.*

P. febanus *Fruhst.* (= jonasi *Rothsch.*, koannania *Mats.*). Agreeing with *P. impediens* in the structure of the genitalia and the colour of the scent-wool. Body more extended red than in *P. impediens*, *mencius* and the forms of *P. alcinous*. Wings similar to those of small *mencius*, but the submarginal spots of the hindwing pale red and very much enlarged above and beneath, almost as long as broad, the large anal spot of the under surface represented above by a distinct pale red transverse streak. — Formosa, in the mountains. *febanus.*

P. alcinous is distributed from Japan to West China and Tonkin. The scent-wool of the ♂ in all the forms is almost black. The harpe has proximally a simple or dentate process and ends distally in a point or a tooth. Larva olive-brown, with numerous dark, light-edged spots; on the 6. and 7. segments a very broad red-white oblique girth, which is dorsally interrupted or strongly constricted; the tips of the tubercles reddish, the upper lateral projections of the prothorax pale red with dark tips. According to Pryer in Japan on Cocculus thunbergi. The butterfly very common, and easy to catch on account of its slow flight; spring to autumn. — In South Yesso, Nippon and Kiushiu occurs the black-headed subspecies *alcinous Klug* (= spathatus *Btlr.*, haematostictus *Btlr.*, nagasakii *Fruhst.*) (vol. I, 2 a). — **loochooanus** *Rothsch.* (19 c ♂, vol. I, 1 c ♀) inhabits the Loo Choo (Riukiu) Islands. Head red. Harpe of the ♂ strongly dentate, as in the Japanese form. — **mansonensis** *Fruhst.* (= mausonensis *Fruhst.*) is a name which may be applied to all the specimens from Formosa, East and Central China (westwards to Chang Yang) and Tonkin. The ♂ not distinguishable from the West Chinese subspecies *confusus Rothsch.*, but the ♀ as pale as in *loochooanus*. Perhaps we should also place here the specimens from the Sannan Islands (Ishigaki-sima), which Oberthür without a description records as *intermedia* and Fruhstorfer later describes as **bradanus;** the wings in the ♀ are said to be narrower and paler and the submarginal spots smaller than in *loochooanus*. — In *confusus Rothsch.*, from West China, the ♀ is darker than in the other subspecies; Oberthür mentions as ab. **decora** an aberrant ♀ which bears two red lines on the underside of the tail. *loochooanus.* *mansonensis* *bradanus.* *decora.*

Coon-Group.

Tail spatulate, with very thin base. Scent-fold of the ♂ only weakly developed; the anal claspers not touching each other above.

Three Malayan species, of which one extends to Burma.

P. neptunus. Breast red at the sides, abdomen greyish yellow from the middle. Forewing black, with a broad light patch before the middle and another one distally to the cell obliquely across the wing; hindwing with very thin tail, much widened at the end, and 2—4 red or pale red spots, placed at a distance from the cell between the median and radial veins and sometimes almost entirely absent in the subspecies from Nias. The butterfly flies slowly and high in the air. — **doris** *Rothsch.* The black basal area of the forewing does not quite reach the base of the 2. median, the black transverse band is very deep black, the grey area very light, before and often also behind the 2. median at least beneath almost pure white, the black fold-streak placed before this vein is far removed from the cell and the one placed behind it only very rarely reaches the black basal area. The hindwing above always with 3 small spots, beneath with 3 or 4, besides the one placed behind the 2. median, which is often whitish above, the anterior spot in many specimens very small. North Borneo, in the plains and hills. — **neptunus** *Guer.* (= thetys *Guen.*) is the transitional form from Malacca, which connects *doris* with *sumatrana*. The light parts of the forewing are similar to those of the preceding subspecies, but the black oblique band is mostly distinctly lighter on the disc, so that the black stripes are visible in it as well as the light ones. — **sumatrana** *Hag.* (16 c). The light parts of the forewing more strongly shaded with black than in the preceding forms, the black fold-stripe placed before the 2. median extending nearly to the cell, the black transverse area almost always lighter and narrower on the disc, so that the light and dark stripes become visible; beneath the *doris.* *neptunus.* *sumatrana.*

two light areas somewhat larger than in the form from Borneo. Hindwing above usually with 2, more rarely
padanganus. 3 spots, beneath mostly with 3, more rarely 2. North-East Sumatra. — **padanganus** *Rothsch.* The black transverse area of the forewing almost as deep black as in the Borneo form, both the proximal and distal light areas narrower than in *sumatrana*, the proximal one narrower than the black transverse area, the black basal area extending to the 2. median, the grey stripe placed behind the 2. median does not reach the cell, the black stripes before and behind this vein as long as in *sumatrana*. Hindwing above in the ♂ with 2 spots, in the ♀ with 3, beneath in the ♂ with 2 large spots and 1 small, and in the ♀ with 3 large and 2 small, besides the dot placed
fehri. behind the 2. median. West Sumatra: Padang Bovenlanden and Padang Sidempoean. — **fehri** *Honr.* (16 c). The forewing very smoky, the dark oblique band much less black than in the other subspecies; hindwing with 2 pale red spots, which above are sometimes only indicated, in a few specimens a small anterior 3. spot is also present in addition, either only beneath or also above. Nias.

P. coon. Black; the head and the sides of the breast red or yellow, the abdomen beneath, laterally and at the tip of the same colour. Forewing narrow, smoky, the margins, veins and folds smoky black; hindwing with spatulate tail, a spot in the cell, which sometimes entirely fills it, but often is reduced to 2 small streak-spots, as well as a row of spots round the cell and a row of submarginal spots white, at the extremity of each of the two median veins a red or yellow marginal spot. Malayan. The butterfly flies in the plains and in hilly country. It is a woodland species and is often taken at the flowers of tall trees. Its flight is fluttering
coon. but rapid. — **coon** *F.* (= hypenor *Godt.*) (16 b). Body and marginal spots of the hindwing yellow; the cell of the hindwing usually entirely or almost entirely filled up with white. Java. — In the most northern part of Java,
patianus. in the Djapara residency, occurs **patianus** *Fruhst.* Forewing of the ♂ broader than in the preceding subspecies, the cell-spot of the hindwing is reduced and sometimes even entirely absent, and the other white spots are strongly
palembanganus. shaded with black. — **palembanganus** *Rothsch.*, from the south of Sumatra. Similar to *coon*, but the submarginal spots of the hindwing smaller, the first and last spots especially being reduced. — Specimens of *coon* from the
delianus. island of Bawean agree with *palembanganus* in the reduction of the submarginal spots. — **delianus** *Fruhst.* (16 b). Body and marginal spots of the hindwing red or yellow-red; cell of the hindwing with 2 white streak-spots. North-
doubledayi. East Sumatra. — **doubledayi** *Wall.* (16 b), from Malacca to Cachar. Spots of the hindwing larger than in *delianus*, the cell-spot very rarely divided. Specimens with reduced spots are ab. **cacharensis** *Btlr.* In the specimens
cacharensis. of *doubledayi* from Lower Burma and Tenasserim both the cell-spot and the first spot (placed before the cell)
sambilanga. are larger on an average than in those from Malacca and Penang. — **sambilanga** *Doh.* occurs on Great Nicobar; according to DOHERTY rather common. The spot placed behind the cell on the hindwing short, both the anterior and the posterior red marginal spot united with the corresponding submarginal spot, as in *P. rhodifer.*

rhodifer. **P. rhodifer** *Btlr.* (16 c). Costal and distal margins of the forewing almost parallel; the wing even in the ♀ considerably narrower than in *P. coon;* the white spots in and at the cell of the hindwing purer white; the two red marginal spots large, united with the submarginal spots, the tip of the tail red. — Andaman Islands; common.

Hector-Group.

With or without tail. Cell of the hindwing about three times as long as broad, much less elongated than in the preceding group. The scent-fold of the ♂ weakly developed or absent, without scent-wool, but sometimes with narrow scent-scales; the anal claspers aborted, but the harpe present.

In the species without scent-fold (*hector*, *jophon*, *pandiyana*, *oreon* and *liris*) the hindmargin of the hindwing is curved downwards in the ♂ as in the ♀.

hector. **P. hector** *L.* (= heroicus *Fruhst.*) (15 a). Head, collar, sides of the breast and the abdomen with the exception of the dorsal plates of the anterior segments red; forewing with two white macular bands, a central one running from the costa to the anal angle and a short apical one; hindwing with two rows of red spots. The ♀ paler than the ♂, especially the red parts of the body and the spots of the hindwing. The full-grown larva brown-black with red tubercles, without oblique band at the sides but with four small reddish white spots on the 6. and 7. segments; on Aristolochia indica. Pupa greyish yellow, the wing-cases strongly projecting. — From Ceylon to Bengal; also recorded from Chittagong on the north-east side of the Bay of Bengal. The butterfly is very common and is often found on low flowering bushes and plants. EUTON states that in autumn, at the beginning of the cold season, the butterfly betakes itself at sunset to trees where it spends the night in hundreds together on the underside of hanging twigs towards their tip, as do many Danaids. *hector* is commonest in low places, but is found singly even at elevations of over 5000 ft.

jophon. **P. jophon** *Gray* (15 a). This species is confined to Ceylon; it is local, but not rare where it occurs, in hilly country from 2000 to 4000 ft. Most easily caught early in the morning; after sunrise it flies high above

the trees. Palpi, sides of the breast and tip of the abdomen red; forewing black, the disc from the point of origin of the 2. median white-grey, semitransparent, this area encroaching on the cell and broken up into spots by the black veins and internervular folds; hindwing with large grey-white area, which is cut off straight proximally and consists of a large cell-spot and 7 spots placed round the cell, a row of red submarginal spots, which are darkened above and rose-red beneath. The ♀ with broader wings than the ♂, otherwise very similar to it. Larva purple-black, with red tubercles, on the 6. segment a yellowish white oblique band, both the tubercles placed in the band also yellowish white. Egg yellow-brown.

P. pandiyana *Moore* (15 a). Similar to the preceding species, much paler, the black distal margin of the forewing narrower, also the black stripes between the radial and median veins extending nearly to the cell. The ♀ has broader wings than the ♂, also the subcostal white spot of the hindwing is reduced and sometimes entirely absent. — A South Indian species, common in the hilly country of Travancore and in the Nilgiris at a height of 1—3000 ft. It flies in the neighbourhood of the evergreen jungle and appears early in the morning in order to drink at flowers, before which it hovers with a fanning motion of the wings, like the allied species. *pandiyana.*

P. oreon. Head, the posterior abdominal segments and the margins of the preceding segments, as well as the sides of the breast at the base of the wings red, the head often pale red. Wings more elongated than in *pandiyana*, especially the hindwing, and its cell much narrower, the tail very feebly spatulate, the grey-white central area of the hindwing, which is shaded with black above, somewhat obliquely cut off basad, the submarginal spots beneath purer red, the black basal area of the forewing does not reach the 2. median, and the cell is almost entirely transparent, with 4 black lines. The butterfly is hitherto only known from Sumba and Alor, but probably also occurs on the neighbouring islands or at least on Flores. — **oreon** *Doh.* (15 b). The black basal area of the forewing extends below the cell about to $^2/_3$ of the distance from the base to the 2. median and the central area of the hindwing is distally rather strongly shaded with black and also of a dull colour otherwise. Sumba. — **godmani** *Röb.* flies on Alor. The base of the forewing is less extended black and the central area of the hindwing is less darkened and more sharply defined, also the 6. submarginal spot above is mostly less strongly blackened and the cell-spot often larger. *oreon.* *godmani.*

P. liris. The black basal area of both wings cut off straight and reaching to the base of the 2. median; distal margin of the forewing more broadly blackened than in *oreon*, the median band of the hindwing distally almost straight, its distal margin somewhat curved outwards in the middle; the hindwing without black discal spot before the subcostal, also the corresponding red or grey-yellow submarginal spot merged together with the median band, rarely separated, and the posterior submarginal spots placed further from the distal margin than in *oreon*. In many forms the red of the body and hindwing is replaced by greyish yellow; the form from Kisser is the transition between the forms with red and those with dirty yellow markings. On all the islands between Timor and Timourlaut, including Wetter and Savu. The butterfly appears to occur all the year round. — **liris** *Godt.* (15 b). Abdomen red and black; the submarginal spots of the hindwing red, the median band above and beneath grey-yellow. Timor, the specimens in the Tring Museum caught in May, July, and November to December. — **gaetus** *Fruhst.* (= savuanus *Rothsch.*). Median band of the upperside of the hindwing thickly shaded with black, with the exception of very few specimens; the band beneath in all specimens somewhat paler grey than in *liris*. The specimens in which the band is not blackened are ab. **pseudoliris** *Fruhst.* Savu Island, our series taken in August. — **wetterensis** *Rothsch.* (15 b). Deeper black than *liris*, the median band of the hindwing much narrower and above shaded with black, the red spot placed before the abdominal margin very long. Wetter, the specimens in the Tring Museum taken in May. — **senescens** *Röb.* Similar to *liris*, but the abdomen and the submarginal spots of the hindwing paler red. Kisser. — **pallidus** *Rothsch.* A pale form; the body and the submarginal spots of the hindwing greyish yellow instead of red; wings above paler than in the preceding subspecies, the median band of the hindwing above strongly shaded with blackish. Letti and Moa, apparently very common. — **aberrans** *Btlr.* (= navigator *Fruhst.*, damaricus *Fruhst.*, velificatus *Fruhst.*). Much less smoky than *pallidus*, the semitransparent central part of the forewing and the median band of the hindwing less blackened, also the submarginal spots of the hindwing stand out more distinctly than the veins and have on the under surface mostly a slightly reddish tone, as has also the tip of the abdomen. Tenimber, Dammer, Roma and Babber; common on Tenimber. The differences mentioned by FRUHSTORFER between the specimens from the various islands are not confirmed by the specimens before us. *liris.* *gaetus.* *pseudoliris.* *wetterensis.* *senescens.* *pallidus.* *aberrans.*

P. polyphontes. Head, the tip of the abdomen and beneath and laterally also the margins of the other abdominal segments red. Forewing in the middle broadly white, this area not reaching the hindmargin and intersected by black veins and folds. Hindwing with broad tail; a white or reddish white central area composed of a cell-spot (cut off straight towards the base) and 5—7 spots placed round the cell, the veins intersecting it rather broadly black; submarginal spots above shaded with black, beneath vivid red, the anterior one entirely white and the others at least edged with white. As in all the allied species the ♀ paler than the ♂. The latter

has the hindtibia thickened, and bears on the hindwing a distinct abdominal fold with a scent-organ; in the ♂♂ of the preceding species of this group the scent-organ is wanting and the hindtibia is not swollen. *P. polyphontes* is the representative of the Indo-Malayan *P. aristolochiae* and the Papuan *P. polydorus;* and has evidently spread again from Celebes to the Sulla Islands and North Moluccas. The butterfly is rather common in flat and *rosea.* in hilly country. — **rosea** *Oberth.* (= extensus *Fruhst.*) is the most southern form known; it inhabits Saleyer Island. The central area of the hindwing has always a distinctly reddish tone above and is somewhat larger than in specimens from Celebes; on the under surface there is always a white spot behind the subcostal of the hind- *polyphontes.* wing, commonly also one before this vein. — **polyphontes** *Bdv.* (= lingonus *Fruhst.*, phanocles *Fruhst.*) (15 a). The ♂ on the upperside mostly more dingy than the ♀; the veins in the light area on both wings broadly black; the black distal margin of the forewing always narrower than the light discal area. SNELLEN mentions an aberration which has yellow instead of red submarginal spots on the hindwing. *P. polyphontes polyphontes* occurs *aipytos.* throughout Celebes and on the Talaut Islands. — In **aipytos** *Fruhst.* (= pedias *Rothsch.*) the light area of the forewing is narrower than in the two preceding subspecies, being in the ♀ pure white, in the cell usually only 2 light stripes, the discal spot placed before the lower angle of the cell much darkened also in the ♀, the black stripes between the veins shorter than in *polyphontes;* on the hindwing the posterior submarginal spots on the upper surface are very little if at all shaded with black. Sulla Islands: Mongola and Besi, a number taken by *sejanus.* DOHERTY in October. — **sejanus** *Fruhst.* (= ithacus *Rothsch.*). The light spots of the forewing smaller than in *polyphontes,* also in the ♀ shaded with blackish, the spot placed before the lower angle of the cell at least partly effaced as in the preceding form; the veins of the hindwing in the white area broadly black. North Moluccas: Halmahera, Morty, Ternate and Batjan.

P. polydorus. A common Papuan butterfly, which is distributed, in many subspecies, from the Moluccas to the Bismarck and Solomon Islands and North Australia. Similar to *polyphontes,* but the hindwing shorter, broader and not tailed, the forewing without white area or this only reaching to the base of the 2. median, the spot placed below this vein longer anteriorly than posteriorly, being obliquely cut off basally. The scent-fold of the ♂ larger than in *polyphontes* and the scales placed in it differently shaped. The larva brownish black, the tubercles red, with the exception of the dorsal tubercles of the 4., 5., 8. and 9. segments, which are brown, on the 6., 7. and 10. segments the dorsal tubercles stand in a pale red spot. Lives on a low Aristolochia and is full-fed in about 14 days. Pupa pale brown, with 4 pairs of dorsal lobes on the abdomen; pupal stage lasts 3 weeks. The butterfly flies in the open shrubby woods low and slowly from flower to flower. The forms from the North Moluccas, New Guinea except the mountains of British New Guinea, and the Bismarck and Solomon Islands have black heads, whilst the South Moluccas, Tenimber, Key, Aru, North Queensland, the Louisiades *septentrionatis.* and the mountains of British New Guinea produce red-headed forms. — **septentrionalis** *Rothsch.* Head and collar entirely black; the light stripes on the upperside of the forewing always shaded with black; the white spots *kajelanus.* of the hindwing distally rounded off. Northern Moluccas: Halmahera, Batjan. — **kajelanus** *Fruhst.* Head and sides of the collar and breast red. Forewing with large white spot behind the 2. median, which as well as the light fork placed before this vein is dusted with black; the anterior white discal spots on the upper surface of the hindwing small, sometimes wanting, the cell-spot in the ♂ mostly dusted with black. Buru, common. *potydorus.* Not constantly different from the following form. — **polydorus** *L.* (= polydotus *Müll.*, leobotes *Deh.*) (15 b). From the South Moluccas (Amboina, Saparoea, Ceram) and Obi, as well as the small islands Goram Laut and Kissoei. The light parts of the upper surface of the forewing on the whole somewhat purer white and more extended than in *kajelanus* and the white spots of the hindwing larger, the 1. discal spot transverse and rhomboidal as in *thessatia.* *kajelanus.* — **thessalia** *Swinh.* Body as in the preceding; forewing purer white; the cell-spot of the hindwing small, in the ♀ often absent; the discal spots on the other hand longer than in *polydorus,* the one placed before the 1. median especially long, the red submarginal spots large, the posterior ones above mostly only slightly *varus.* blackened. On Little and Great Key, very common. — **varus** *Fruhst.* Not distinguishable with certainty from the Key form. The posterior white spot of the forewing mostly somewhat smaller than in *thessalia,* the part of this patch placed behind the submedian fold sometimes wanting, the light stripes on the whole less sharp, the *tenimberensis.* central ones more strongly darkened. Aru Islands. — **tenimberensis** *Rothsch.* Head black, mixed with red; the stripes of the forewing and the large patches placed between the 1. median and the 2. submedian pure white; the white area of the hindwing large, the veins intersecting it very narrowly black at least on the cell; the posterior ones mostly distally reddish, the 1. white spot smaller than the 2., the 4. the largest. Tenimber Islands. — *queenslandicus.* **queenslandicus** *Rothsch.* Similar to small specimens of *polydorus,* the white markings of the forewing shorter, the spot placed behind the 2. median beneath very strongly pointed posteriorly; the hindwing almost always with 6 white spots outside the cell, most specimens in addition with a linear spot on the proximal side of the 1. *aignanus.* submarginal spot. North Queensland and the islands in the Torres Straits. — **aignanus** *Rothsch.* Likewise a small form. The white spots of the forewing larger than in *queenslandicus;* the cell-spot of the hindwing small; 5 spots at the cell, the 1. small, sometimes wanting, the 2. about twice as long as broad, the 4. the largest, but not reaching the base of the 2. median and only a little larger than the 3. spot. Louisiade Islands: St. Aignan *orinomus.* and Sudest. — **orinomus** *Rothsch.* In the hilly country of British New Guinea occurs a form very similar to the preceding. The cell-spot of the hindwing much larger than the 2. white discal spot, and the 4. discal spot larger

than the 3., also the 5. submarginal spot is smaller than in *aignanus*, sometimes even smaller than the 4.; the 4. discal spot usually reaches the base of the 2. median. From the higher elevations of British New Guinea; in lower parts of the same district occurs a black-headed form (*naissus Fruhst.*). — In the following forms the head and thorax are entirely black, very rarely with some red hairs behind the eyes. — **leodamas** *Wall.* The black basal part of the forewing is not sharply divided from the striped discal part, and the light stripes are also beneath very indistinct; the cell-spot of the hindwing and the 1. white discal spot likewise very small, narrow, the latter above sometimes absent, the other 4 spots long, the last two not quite reaching the base of the 2. median, the diameter of the 6. red submarginal spot on the underside longer than the distance of the spot from the white area. *leodamas.*
Misol. — **godartianus** *Luc.* (= papuana *Oberth.*). The grey stripes on the under surface of the forewing indistinct, also the posterior black vein-stripes and interneural stripes extending nearly to the cell, the black basal half of the wing is however sharply separated from the distal half. Hindwing similar to that of *leodamus*, above sometimes only 4 white spots present, as the cell-spot and the 1. discal spot are not always developed. Arfak and Onin Peninsulas; Salawatti and Etna Bay. — **asinius** *Fruhst.* Forewing in the ♀ with large white patch before and behind the 2. median, in the ♂ the spots as well as the light stripes above rather strongly darkened, beneath on the contrary white; the white area of the hindwing large, distally rounded, the cell-spot mostly smaller and the other spots longer than in the form *plagiatus*, from German New Guinea, which also bears a white patch, the 1. discal spot longer than broad, the 4. the largest. The red of the abdomen in the ♀ somewhat more extended than in *plagiatus*. Waigeu. — **meforanus** *Rothsch.* Forewing above in the ♂ with narrow dark grey stripes, in the ♀ with thin white ones, before and behind the 2. median, beneath on the contrary in both sexes these stripes are widened into white spots, also the other stripes are more distinct than above. The white area of the hindwing is much smaller than in *asinius*, the cell-spot being about three times as large as the 1. discal spot, which is small, the 4. spot anteriorly (at the 1. median) less than twice as long as it is broad distally. Mefor in Geelvink Bay. — We have a single ♀ from Jobi in Geelvink Bay, which has much white on the forewing above and beneath, and in which also the white area of the hindwing, especially the 1. discal spot, is large. But according to Kirsch's description of 3 specimens from Jobi (evidently ♂ ♀) these characters do not hold for all specimens. — **humboldti** *Rothsch.*, from Humbold Bay at the boundary of Dutch and German New Guinea, forms the transition to the following subspecies. The grey stripes on the under surface of the forewing are narrow and dark, the black vein-stripes are broad and extend to the cell and the fold-stripes almost touch them; beneath on the other hand the pale stripes are very light, the posterior ones white and before and behind the 2. median united into patches, yet the black stripe of the 2. median and the fold-stripe placed before it remain long. The cell-spot of the hindwing often very small, smaller than the 1. discal spot, the latter on the upper surface anteriorly mostly incised, beneath always rhomboidal, which is often also the case above. — **plagiatus** *Rothsch.* Forewing in both sexes beneath always, above often bearing much white; the 2. median inside the white area only very narrowly black, the fold-stripes placed before and behind this vein short. Cell-spot of the hindwing larger than the 1. discal spot, the 4. and 5. discal spots reach to the base of the 2. median, the 5. often extends still further basad and is also somewhat prolonged distally; the white area distally less rounded than in *asinius*. German New Guinea: Astrolabe Bay and Huon Gulf. — **naissus** *Fruhst.* (= albosignatus *Fruhst.*, phalces *Rothsch.*). Forewing as in *plagiatus;* the white area of the hindwing mostly more rounded, the cell-spot smaller, the 1. discal spot usually oblong, the 4. and 5. spots not quite reaching the base of the 2. median, all the spots mostly rounded off distally. Trobriand and Fergusson, d'Entrecasteaux Islands; British New Guinea. Some of the specimens from the latter district cannot be distinguished from *plagiatus*. — **dampierensis** *Hag.*, from Dampier Island on the north coast of German New Guinea. Forewing above dark, beneath with white. The white area of the hindwing above narrowed to a band, the small cell-spot and the 1. discal spot strongly and the 2. and 3. discal spots slightly shaded with black; the white area beneath only a little narrower than in *plagiatus*, the 4. and 5. discal spots not quite reaching the base of the 2. median. the submarginal spots large, also the one united with the last discal spot. — **novobritannicus** *Rothsch.* Forewing lighter than in *plagiatus;* the cell-spot of the hindwing large, the discal spots on the contrary small, especially the 2. and 3., which are often wanting in the ♂. Abdomen laterally more extended red, also the 2. and 3. segments laterally edged with red, on the other hand the 7. segment above with a black spot. New Pomerania (= New Britain). — **utuanensis** *Ribbe.* Forewing much darker than in the preceding subspecies; the white area of the hindwing more rounded, the cell-spot smaller and the discal spots longer. New Lauenburg and New Mecklenburg (= Duke of York and New Ireland). Not constantly different from the next form. — **polydaemon** *Math.* (16 a). In the specimens from the northern Solomon Islands Bougainville, Alu and Treasury the grey stripes of the forewing above are dark and beneath rarely united into grey-white patches before and behind the 2. median, also the cell-spot of the hindwing is mostly small (ab. **polypemon** *Math.*). The specimens taken on the islands more to the south on the contrary are mostly lighter, especially in the ♀ and particularly on the under surface, also the white spots of the hindwing are larger in many specimens. The anterior submarginal sports of the hindwing beneath are often very pale in *polydaemon*, and the 1. is commonly partly edged with white, which occurs especially often in northern specimens; in some specimens in the Tring Museum (also in one *utuanensis*) the 2. and 3. submarginal spots are united either on both wings or only on one. So far no specimens are known from the most southerly Solomon Islands (San Christoval and Rennel).

humboldti. *plagiatus.* *naissus.* *dampierensis.* *novobritannicus.* *utuanensis.* *polydaemon.* *polypemon.*

P. aristolochiae. The tip and sides of the abdomen and the margins of the ventral segments red, and also the sides of the breast and the head. Forewing from the base to about the 2. median and at the margins black, the disc usually more or less lighter, with black fold-stripes. Hindwing with spatulate tail, which is sometimes reduced to a tooth, and red submarginal spots, which above are more or less strongly shaded with black; in the middle often a white area. The ♀ paler and with broader wings than the ♂. Larva black, with red fleshy tubercles; on the 6. segment, which bears the 1. pair of prolegs, a white girth; the tubercles in this likewise white; according to MARTIN the milk-white girth is sometimes wanting in Sumatra; on Aristolochia indica and bracteata (according to HAGEN also on Piperaceae). Pupa with 4 pairs of rounded lobes on the abdomen, the lateral lobes of the thorax likewise rounded. A common butterfly, which flies especially in the plains and hills and seldom ascends above 4000 ft. It occurs from the Loo Choo Islands, West China and Ceylon eastwards and southwards to the Lesser Sunda Islands, in wooded districts and in gardens, but not in thick forests. Its flight is slow and heavy. The butterfly visits flowers and is sometimes taken in crowds on flowering trees, especially in the early morning. The peculiar distribution of the two principal types in which the butterfly occurs,

camorta. the black and the white-spotted type, is very interssting. — **camorta** *Moore* (16 a), from the Nicobars. Hindwing with a white spot at the cell between the two median veins and a red one behind it; on the under surface

ceylonicus. in addition two smaller spots at the apex of the cell and a third in the cell. — **ceylonicus** *Moore.* Forewing at least beneath very light, the black stripe placed behind the 2. median almost always shortened; the white spots of the hindwing close to the cell, the middle ones distally rounded off, the cell usually with a white spot. Ab-

aristolochiae domen of the ♀ with the exception of the last segment mostly entirely black above. Ceylon. — **aristolochiae** *F.* (= polidorus *Cr.*, polydorus *Godt.* nec *L.*) (16 a). Forewing from the base to beyond the point of origin of the 2. median black, the stripes placed between the 2. median and the hindmargin rarely shortened; hindwing always with white spots but always without cell-spot; the spot placed behind the 2. median on the under surface not

diphilus. emarginate on the side nearest this vein. In f. **diphilus** *Esp.* the white spots are placed near to the cell, whilst in f. **aristolochiae** *F.* they are reduced from the basal side and therefore remote from the cell. The small-spotted specimens fly at the same time with the large-spotted ones, but appear to be the commoner form during the hot rainy season (summer). MOORE erroneously regarded the large-spotted specimens as „wet form." South, North-West and North-East India. The butterfly is called in Calcutta Rose Butterfly on account of its strong scent. —

adaeus. In West, Central and East China southwards to about Fu-chow flies **adaeus** *Rothsch.* Very similar to the preceding subspecies, but the ♀ paler, the hindwing in both sexes longer and the white spots differently developed. These spots usually small, but placed near the cell, the spot before the 1. median usually $^1/_3$ to $^1/_2$ and never more

interpositus. than $^2/_3$ as long as its distance from the corresponding submarginal spot. — **interpositus** *Fruhst.* is the usual form on Formosa. It has large submarginal spots on the hindwing; the white band is placed near to the cell without entering it, and the spot placed before the 1. median is about as long as its distance from the corresponding submarginal spot, or somewhat shorter. On the forewing the dark basal area extends beyond the base of the 2. median;

formosensis. the ♀ is mostly very pale above. According to Dr. REBEL a black form also occurs on Formosa: **formosensis** *Reb.* Similar to *lombockensis*, forewing in the distal part not pale, the red submarginal spots on the underside of the hindwing thin, some of them also developed above; tail long, spatulate. Whether *formosensis* and *interpositus*

rhodopis. fly in the same districts or are geographically separated, is not known to us. — **rhodopis** *Rothsch.*, from the Liu Kiu Islands (= Loo Choo), is very similar to *interpositus*, but on the under surface of the hindwing the 1. white spot anteriorly and the 2. and 3. are shaded with red in the centre between the veins at least at the margins. —

goniopeltis. **goniopeltis** *Rothsch.* From Hong-Kong southwards to Siam, Burma and Tenasserim flies a form which recalls the Philippine subspecies *philippus*. On the forewing the black basal area extends to the point of origin of the 2. median; between this area and the black distal margin the wing is very pale beneath; the white spots of the hindwing are always placed at the cell and very rarely reduced, the one before the 1. median is usually pointed and mostly very long, many specimens have a small cell-spot; on the underside the last spot is usually entirely red, also the veins separating the spots are frequently reddish, as well as the spots themselves. The tip of the

asteris. abdomen is on the whole more extended red than in *ceylonicus.* — **asteris** *Rothsch.*, from the Malay Peninsula and the island of Penang. On the whole smaller than the preceding subspecies, the abdomen fully as red, the upper surface of the wings deeper black, the ♀ almost as dark as the ♂; the white spots of the hindwing close to the cell, usually narrow, the spot placed before the 1. median always shorter than its distance from the corresponding submarginal spot; the 1. discal spot often absent, always linear if present and placed close to the cell; the 2. and 3. spots likewise often linear, the cell above often and beneath usually with small spot; the submarginal

antiphus. spots small. — **antiphus** *F.* Hindwing without white spots, tail spatulate. Sumatra, Nias, Natuna Islands, Borneo and Djampea (south of Celebes). On the Natuna Islands single specimens also occur which are very similar to the subspecies of *aristolochiae* from Siam, Burma, Tonkin, etc., but the hairs on the frons are strongly mixed with black, the hindwing bears three long white spots and one of our two specimens (♂♂) has also another small white dot before the 2. radial; in this specimen the tail is spatulate, in the other short and narrow, which is also the case in some black specimens from the Natunas. The white-spotted form is probably

atavus. a reversion: ab. **atavus** *ab. nov.* In the Tring Museum there are also a number of specimens from Bunguran (Natuna Islands) in which the white markings are only indicated. In ab. *atavus* the red submarginal spots are larger than in most specimens of *antiphus*, also the spot placed behind the white markings is large. Black specimens

with narrow tail are ab. **acuta** *Druce* and specimens with quite short tail ab. **periphus** *Oberth.* (= brevicauda *Stgr.*); both forms occur singly among normal *antiphus* on the Natuna Islands and on Borneo, but are not known from Sumatra; on the other hand on Palawan no specimens with spatulate tail seem to occur. — **antiphulus** *Fruhst.*, from the Sulu Islands, is a large race, which recalls *kotzebuea*. The forewing is rather pale, the posterior black stripes of the under surface are narrow, there are no red spots between the 7. red spot of the hindwing and the apex of the cell beneath. — **kotzebuea** *Eschsch.* (= polybius *Godt.*) (16 a) inhabits the western Philippines: Mindoro, Luzon, Polillo, Bohol and Cebu. Almost all specimens have on the hindwing a red band, sometimes white in parts, extending from the apex of the cell to the abdominal margin. The specimens of the rainy season are dark, those of the dry season lighter. — The south-eastern Philippines are inhabited by **philippus** *Semp.* A broad-tailed form with 3—5 white discal spots on the hindwing. — **adamas** *Zink.* (= thoas *Swains.*; mamilius *Fruhst.*). Flies on Java, Bawean and Engano. The long hairs of the frons are black; the median white spots of the hindwing are placed close to the cell, there are always (?) 5 spots present including the one placed behind the 2. median; the cell apparently never has a spot. Single specimens of *antiphus* also occur on Java. — **balinus** *Fruhst.*, from Bali. The median white spots of the hindwing a very little shorter than in *adamas*, otherwise not different from *adamas*. — **antissa** *subsp. nov.* Forewing beneath somewhat more broadly black at the distal margin than in *adamas*. The submarginal spots of the hindwing large, the posterior ones reniform; the white band consists of 4 spots including the double spot placed behind the 2. median, which is red in the ♂, red-white in the ♀. A pair from Kangean, collected by PRILLWITZ in August—September. — On Lombok occurs again a dark form, in which only now and again small white spots are present, which at least on the upper surface are shaded with black: this is **lombockensis** *Rothsch.* (= lombokensis *Fruhst.*). The forewing above is not so light as in *antiphus* and beneath is more broadly black at the distal and hindmargins. — Sumbawa on the contrary is inhabited by a white-spotted form, which is very constant: **austrosundanus** *Rothsch.* In this there are always only 3 discal spots on the hindwing in addition to the red spot placed before the hindmargin; the 1. and 3. spots are small, the 2. is twice or three times as long as broad and at most $^3/_5$ as long as its distance from the corresponding submarginal spot. — The most easterly locality for a form of *P. aristolochiae* is Flores. Here is found **floresianus** *Rothsch.* In the Tring Museum there are 3 specimens taken in the dry season, resembling large specimens from Java. The white area of the hindwing consists of 5 spots, of which the 1. is small and streak-shaped, whilst the others are large; the third of these spots is almost as long as its distance from the corresponding submarginal spot, the 1. to 4. spots are pure white, the 5., which is placed before the hindmargin, is red or reddish and not incised behind the 2. median; the submarginal spots are paler red above and beneath than in *austrosundanus*.

acuta. periphus. *antiphulus.* *kotzebuea.* *philippus.* *adamas.* *balinus.* *antissa.* *tombockensis.* *austrosundanus.* *floresianus.*

P. annae. Head, sides of the thorax and the greater part of the abdomen grey-yellow or red. Forewing from the base to the 2. median and at all the margins black, otherwise semitransparent; with black stripes at the veins and folds; hindwing with spatulate tail, the white area intersected by black veins, more than half the cell white; the submarginal spots grey-yellow or the posterior ones red, above shaded with black. Mindanao and Mindoro. — **annae** *Fldr.* (15 c), from Mindoro, is the larger form, in which the white area of the hindwing has a yellowish tone. Red-bodied specimens may be distinguished as ab. **erythrus** *ab. nov.* — **phlegon** *Fldr.*, from Mindanao and Guiamaras, is smaller than *annae*, the white area of the hindwing has a bluish (milk-white) tint, and the spots are smaller. The abdomen appears always to be reddish. Both subspecies are very rare in collections.

annae. *erythrus.* *phlegon.*

P. mariae. Frons black, sides of the breast and tip of the abdomen red, the latter especially at the sides. Forewing similar to that of *P. annae*, the dark margin less sharp and the black basal area posteriorly much broader. The white cell-spot of the hindwing does not quite reach the point of origin of the 2. median; 4 or 5 white spots round the cell, of which the 3 middle ones are larger than the cell-spot; tail strongly spatulate; some of the submarginal spots on the under surface edged with white. Philippines; rare. — **mariae** *Semp.* (15 c) has 5 white spots on the hindwing besides the cell-spot. Bohol, Cebu and Mindanao. — In **almae** *Semp.* there are only 4 spots at the cell of the hindwing, as the last spot, which in *mariae* is placed behind the 2. median, is wanting. Polillo; 2 specimens in SEMPER's collection in the Frankfort Museum Senckenberg, taken in October and November.

mariae. *almae.*

P. phegeus *Hopff.* (15 c). Head, sides of the breast and the greater part of the sides of the abdomen red. Forewing as in *mariae*, but the distal $^2/_3$ darker. Hindwing without cell-spot, 3 white spots at the cell and further a white dot behind the 2. median; above 3 or 4 red submarginal spots besides the very small red spot placed behind the white area, the posterior spot very large; beneath 5 or 6 submarginal spots. — Described from „Luzon", but only found by SEMPER on Samar, Panaon and Mindanao.

phegeus.

P. schadenbergi. Body similar to that of the preceding species. Forewing lighter; hindwing only with submarginal spots. In North Luzon and on the Babuyanes. — In **schadenbergi** *Semp.* (15 c), from North-West Luzon and the Babuyanes, the anterior submarginal spots are white and the posterior ones red; the forewing

schadenbergi.

micholilzi. is very light, being yellowish white behind. — **micholitzi** *Semp.* is much more smoky, and the submarginal spots of the hindwing are all or almost all white or whitish. North-East Luzon. — Like most of the Philippine butterflies except the very common species, *schadenbergi* is still rare in collections. Nothing is yet known as to the habits and the earlier stages of this Papilio. Probably it inhabits shrubby woods like *P. polydorus*.

atropos. **P. atropos** *Stgr.* (16 b). Body as the preceding. Both wings smoky black; forewing semitransparent almost to the base; hindwing not transparent, with slight indications of paler submarginal spots. — Palawan.

B. Fluted Papilios.

Antennae without scales; the segments somewhat thinner towards their bases; the fine sensory hairs either pretty equally distributed over the ventral surface of the segment or concentrated on two large, lateral, non-impressed areas. The tarsi likewise without scales, the dorsal spines separated from the rows of the under surface by a lateral, impressed, spineless longitudinal stripe. The abdominal margin of the hindwing in both sexes is simply curved downwards and forms a groove beneath. The hindwing of the ♂♂ has no scent-organ, as in almost all the Aristolochia Papilios and Kite Swallowtails, on the other hand there are scent-scales on the forewing of many species of the Old World (in no American forms). In the Indo-Australian forms the wings of both sexes are always thickly scaled, also almost all the species have at least a few metallic (grey, green or blue) scales. The head and breast are mostly spotted with white, sometimes almost entirely black, more rarely with red or yellow markings, but the red always dull, never so glaring as in Aristolochia Papilios. — The young larvae resemble bird-droppings and bear on each segment more or less distinct humps or spines, which in most species disappear later. According to the markings we have 2 principal types of larvae: the spotted larvae (*P. machaon*, *elylia*, *anaelus*, *laglaizei*, etc.) and the oblique-banded larvae (*P. xuthus*, *polytes*, *memnon*, *aegeus*, *bianor*, etc.). This 2. type is the normal one. Very many larvae live on species of Citrus, and Xanthoxylon is also a favourite food-tree. The pupa rough and leathery, usually resembling a piece of wood, the head mostly prolonged into 2 horns, which are rough on the innerside; the thoracic horn usually short, in some forms nevertheless very long and curved backwards (*P. demolion*); the wing-cases not so strongly dilated as in the Aristolochia Papilios, commonly scarcely projecting laterally; the dorsal protuberances of the abdomen are absent or very small.

The Fluted Papilios have a wider distribution than the other Papilios and are also richer in species. One species extends to the arctic zone and ascends in the high mountains to beyond the tree-limit (*P. machaon*; in the Andes of South America the nearly allied *P. polyxenes americus*). The butterflies are much less tenacious of life than the Aristolochia Papilios; the thorax is brittle. A great number of the species are mimetic in the ♀ or in both sexes, and it is worthy of note in this respect that one group of nearly allied species appear only in the garb of Danaids, whilst a second large group show only imitations of Aristolochia-Papilios and *Tenaris*. In addition there are a few forms which resemble *Aeraea* and *Nyctalemon*. A large series of black forms with white or yellow markings are not mimetic, and a further large group is dark on the under surface like bark or dried leaves, above on the contrary adorned with the most glittering blue or green.

We begin with the Danaid-mimics, place the forms less specialized in their markings in the middle, and leave the metallic species (*P. ulysses*, etc.) to the last, in which way it will best be possible to place the species which unite these principal groups together with their allies.

1. Mimics of Danaids.

Body spotted with white, the mesothorax above at least with a couple of white dots, the abdomen beneath with 3 rows and at the sides with 2 rows of these dots, the uppermost row sometimes obsolete, in other cases with the lower lateral dots so merged together that the abdomen is ringed with black and white; hindwing at the base with a white dot or spot, usually also a spot of the same colour at the base of the forewing. Markings like Euploeids and Danaids, with the exception of the ♂ of *P. eastor*. Larva almost cylindrical, with reddish dots, larger light longitudinal patches and 2 or 3 rows of spines; the larvae of the *eastor* group on the contrary are oblique-banded larvae, similar to that of *P. polytes*. Pupa likewise almost cylindrical, similar to a broken-off twig; the wing-cases scarcely projecting at all laterally; head truncate, not produced into horns, the thoracic horn low, directed forwards; thorax and abdomen above with 4 rows of small round tubercles, the abdomen flattened beneath and hollowed out, lying close to the twig on which the pupa is fastened, the pad for the cremaster very strong.

Agestor-Group.

The subcostal of the hindwing branches off from the cell further distally than the lower median.

P. agestor. A copy of *Danaus tytia*. Abdomen with large light transverse spots. Forewing for the most part whitish grey, the veins, an oblique band in the apex of the cell and the distal margin black; hindwing brownish yellow, more vivid in the living insect; the veins and the distal margin often black, the cell, a stripe before and

beneath it as well as 2 or 3 rows of spots between cell and distal margin white-grey. Beneath almost as above. The ♀ similar to the ♂, but the wings somewhat broader. Larva with 4 rows of spines; above blackish brown, beneath pale yellowish, with 3 pairs of large pale yellowish longitudinal patches edged with black, of which the 2. and also the 3. pair are joined above; red and black dots between the patches; the young larva rests on the upperside of a leaf and is marked like bird-droppings; on Machilus odoratissimus and perhaps on other Laurineae. The butterfly in shrubby woods; it skims lightly over the tops of the bushes without flapping the wings, and always returns again to the resting-place it has once chosen, on a projecting twig, even when it has been more than once disturbed. North-West India to Malacca, Central and South China, up to 6—7000 ft.; only in the spring; the pupa hibernates. — In Central and South China flies **restricta** *Leech* (= tahmourath *Ehrm.*, agestorides *Fruhst.*) (see vol. I, p. 13, pl. 7 b). The cells of both wings with black stripes; veins and distal margin of the hindwing black, an area on the hindwing extending from the abdominal margin to the cell brownish yellow. The ♀ quite similar to the ♂. — **matsumurae** *Fruhst.* Strongly darkened throughout, hindwing black instead of red-brown from the margin to the cell. Formosa. Not known to me in nature. — **govindra** *Moore* (= gopala *Moore*) (vol. I, pl. 7 b). Hindwing with broad black stripes between the veins from the distal margin towards the disc, sometimes in the ♂ almost the whole wing black except for the grey markings, in the ♀ on the contrary the black sometimes almost all suppressed. North-West India. — **agestor** *Gray* (= senchalus *Fruhst.*, cresconius *Fruhst.*) (20 a). With the exception of the grey markings the hindwing is entirely brownish yellow, but often rather dark on the disc. Mostly larger than *govindra*. Nepaul, Sikkim, Assam, Burma, Tenasserim, Upper Tonkin, and Perak (?). I doubt whether a ♀ in the Tring Museum, taken by Doherty, which bears the label Perak, really comes from there; the collection in question did not reach the Museum direct from the collector.

restricta. *matsumurae.* *govindra.* *agestor.*

P. epycides. Wings white-grey, with black vein-stripes and black distal margin, in the latter on the forewing one row, and on the hindwing two rows of grey-white spots; a round anal spot on the hindwing yellow. The ♀ purer and more extended grey-white than the ♂, the forewing broader. West China, Sikkim, Assam, Burma and Tenasserim. In the spring; only one brood; the butterfly in sandy river-beds. — **horatius** *Blanch.* (see Vol. I, 8 b) is the darkest form; from West China and (the same form?) Formosa. — **epycides** *Hew.* (29 c). ♂: all the whitish spots on the forewing placed distally to the grey discal stripes sharply outlined; the width of the black vein-stripes very variable, in some specimens almost twice as broad as in others from the same locality. In the ♀ the black stripes are narrower than in the ♂ and the grey markings lighter. Sikkim, Bhutan and Assam; a series of both sexes in the Tring Museum. — **curiatius** *Fruhst.* (= curatius *Fruhst.*, curiatus *Moore*), from Upper Burma, which is not known to me in nature, has according to the description broader black vein-stripes than *epycides*, also the grey discal stripes are darker. — **hypochra** *subsp. nov.* The ♂ as light as light ♀♀ from Assam and Sikkim, the 3 grey discal stripes on the forewing above, which are placed between the lower angle of the cell and the 2. median, distally twice as broad as the black vein-stripes; the costal margin of the forewing, especially beneath, more narrowly black than in *epycides*-♂♂, and the under surface of the hindwing before the cell with a long, broad white-grey stripe, which extends almost to the submarginal spot, the costal margin from the base to the middle likewise white-grey. One ♂ from the Shan States and another from the Karen Mountains (Salwin River) in the Tring Museum.

horatius. *epycides.* *curiatius.* *hypochra.*

P. slateri. Body black, abdomen beneath with 3 and at each side with 2 rows of separated white dots. Wings dark brown, margins entire, without a trace of fringe-spots; upper surface of the forewing with or without blue or white discal stripes; hindwing always with a yellow marginal spot at the anal angle, as in *epycides*, and commonly with white discal stripes. The ♀ quite similar to the ♂. Distributed from North India to Sumatra and Borneo. Like the two preceding species in North India and Burma a spring butterfly, which only flies in one brood. The butterfly has quite the slow flight of the Euploeids whose garb it wears, and occurs principally in low situations. Nothing is yet known about the early stages. — **slateri** *Hew.* (20 a). Forewing with whitish blue discal stripes between all the veins, which are sharply defined distally, and a cell-spot of the same colour; hindwing without white stripes before the distal margin, or these beneath or on both sides distinct. These white-striped specimens are ab. **jaintinus** *Fruhst.* The butterfly is rather rare in Sikkim, commoner in Assam. Sikkim; Assam (Khasia, Jaintia and Naga Hills); Upper Tonkin (Van-bu, in the Tring Museum); not yet recorded from Upper Burma, where it doubtless occurs. — **marginata** *Oberth.* Stripes of the forewing as distinct as in the preceding form, but shorter and narrower; hindwing above and beneath with a band of white streak-spots. In one of the two ♂♂ from the southern Shan States in the Tring Museum these white patches are entirely absent above, and beneath there are only slight indications of some of them: ab. **cnephas** *ab. nov.* South Tonkin, Central Siam and Shan States. — **tavoyanus** *Btlr.* (= clarae *Marsh.*). The blue patches of the forewing much more reduced than in *marginata*, indistinct, sometimes only traces of the stripes present; hindwing with a band of white stripes as in *marginata*. Tenasserim. — **perses** *Nicév.* (= sumatrana *Hagen*, persoides *Fruhst.*). Forewing without blue markings, but beneath before the hinder angle with slight traces of white patches; hindwing always with white streak-spots, which vary individually in length and breadth. The ♀ unknown, probably very similar to the ♂ as in the other forms. Two aberrant specimens of the ♂ are known, which differ somewhat from one another and have been described as two separate species: ab. **petra** *Nicév.*, forewing with white discal stripes; North-West Sumatra; the genitalia of the specimen do not differ from those of the usual Sumatra form *perses*.

stateri. *jaintinus.* *marginata.* *cnephas.* *tavoyanus.* *perses.* *petra.*

sticheli. In ab. **sticheli** *Tetens*, from Perak, the white stripes are longer and there is a bluish white spot in the cell of the
hewitsoni. forewing. Malacca and North-East and West Sumatra. — **hewitsoni** *Westw.* (20 b) is very similar to the preceding subspecies; the forewing has beneath before the hinder angle no trace of white spots and the hindwing is at least above without white streak-spots or these are much obscured; specimens with such white stripes on the hindwing
persides. are ab. **persides** *Fruhst.* (= persoides *Fruhst.*). North Borneo, principally in the hills.

Clytia Group.

The subcostal vein of the hindwing branches off about in the basal third of the cell and is therefore placed nearer to the base than is the lower median branch; the cell of the hindwing narrow and as in the similarly marked Kite Swallowtails (*P. macareus*, *megarus*, etc.), somewhat incurved between the subcostal and 1. radial.

Some of the species which belong here are very strikingly dimorphic in both sexes.

P. clytia. ♂ and ♀ quite similar. Frons always with 2 white spots; both wings with light marginal spots; the hindwing always sinuous between the veins. The white spots of the abdomen in the light forms merged together into longitudinal lines, in the dark forms usually separated and those of the subdorsal row small and partly suppressed. In most districts two principal forms, one resembling *Euploea* and the other *Danaus*, both variable in themselves, especially the dark one, which is modelled on various Euploeids. In other districts on the contrary only a single form. Whilst on the Andamans and Timor with the neighbouring islands only mimics of *Danaus* occur, on Palawan and the Philippines on the other hand there are only Euploeid-mimics. From the large Sunda Islands (Sumatra, Borneo and Java) this species is not known; it is there represented by *P. paradoxa*, which occurs together with *P. clytia* from Malacca to Assam. These butterflies are not only deceptively like their Danaid models in form and colouring, but have also the same slow flight; when pursued, however, they fly with greater swiftness. The two principal forms are about equally common in all places where both occur. The butterfly is principally found in the plains and only ascends in the hills to 3000 or 4000 ft. It is taken in large numbers at puddles and on the sandy banks of brooks and rivers and also at flowers. The young larva deep black, a large patch on the two last segments, a saddle-spot in the middle of the body and from this to the 1. segment a lateral stripe composed of spots milk-white, a lateral line above the legs yellowish, on the 1.—4. segments at each side two rows of club-shaped spines, on the other segments one row, at each side 2 rows of round spots; the full-grown larva likewise deep black, without distinct line above the legs, the dots bright red, the spines sharp, the fork on the neck pale coloured; on various Laurineae, as Tetranthera, Alseodaphne, Cinnamomeum, etc. The pupa similar to a broken, dry twig. The butterfly all the year round, except during the winter in the
clytia. northern districts. — **clytia** *L.* (see vol. I, pl. 7 a). Dimorphic and each of the two principal forms again very variable within itself. The different forms were formerly regarded as species, but there is not the least doubt that they all belong to one species: the *Euploea*-like form has been found in copula with the one similar to *Danaus*, the larvae of the two are alike and occur together, and there are no structural differences at all to be found in the butterflies. We even treat all the examples from Ceylon, India, China, Formosa, Hainan, Tonkin, Siam, Malacca and Singapore as belonging to one geographical race, there being no tenable differences between the specimens from the different districts. On the other hand the degree of variability and the character of the variations are by no means the same everywhere; on Ceylon, for instance, both forms are comparatively very constant, in North India, Burma, Siam, etc., very variable; some varieties are only known from one country,
dissimilis. others only from another. We have to do here with the beginning of a separation into geographical races. f. **dissimilis** *L.* (20 d), wings black, from the base with yellowish white stripes and before the distal margin with spots of the same colour; the ♀ on the whole lighter than the ♂. The width of the stripes varies considerably and they are commonly dusted with black. Very common in the whole area of distribution; the specimens from
commixtus. the different districts not distinguishable. f. **commixtus** *Rothsch.* (31 d) we only know from Sikkim and Assam; forewing brown-black, with very faint stripes on the disc and smaller spots before the distal margin; hindwing
casyapa. striped almost as in *dissimilis*, but the cell for the most part pure brown-black. In f. **casyapa** *Moore* the forewing is brown-black and has besides the marginal spots 2 rows of patches, of which the proximal ones are usually diffuse; hindwing from the base to beyond the apex of the cell black-brown, in the distal half with discal arrow-spots, submarginal angular spots and mostly yellowish marginal spots; North India. The upper surface of f. **clytia** *L.*
saturata. (20 c) almost black; the forewing with a row of spots before the distal margin; South China, Siam. f. **saturata** *Moore* resembles *clytia*, but the discal spots of the hindwing are very short and diffuse; from South China and
papone. Hainan. In f. **papone** *Westw.*, which is black-brown above, the forewing has no patches; from Tenasserim and
janus. Siam. On the contrary in the otherwise quite similar form f. **janus** *Fruhst.*, from Tenasserim and Siam, the submarginal spots of the forewing are black, commonly with white centres. The somewhat paler brown
panope. specimens with a row of spots before the distal margin of the forewing are f. **panope** *L.*; from China, Tonkin,
onpape. Siam, Tenasserim, North, North-West and South India. In f. **onpape** *Moore*, which is usually still paler, one or several spots at the apex of the forewing are prolonged to the distal margin; commonest in Tenasserim, but
lankeswara. also occurring in Burma, Siam, Tonkin and Formosa. An equally pale brown form is f. **lankeswara** *Moore* (= cly-

tioides *Moore*) (20 b), in which all the submarginal spots of the forewing are small; Ceylon, South India, Tenasserim, Singapore; this is the only variety occurring in Ceylon except f. *dissimilis*. **P. lacedemon** *F.*, described from Malabar, which is not known to me in nature, probably also belongs here; it is above entirely blackish brown with white marginal spots and bears on the underside of the hindwing a row of black submarginal lunules. *lacedemon.* Besides the before-mentioned varieties, which are principally based upon differences in the ground-colour and the patches of the forewing, there are also naturally many individual forms which are distinguished in addition in the marking of the hindwing; the most striking of these aberrant forms are those in which the light marginal spots of the hindwing above and beneath are suppressed or very strongly enlarged. — The following geographical races are all monomorphic. On the Andamans flies **flavolimbatus** *Oberth.* (20 d). Similar to f. *dissimilis*, but the yellow submarginal spots of the hindwing larger; the genitalia are also somewhat different. — **panopinus** *Stgr.* (20 c), from Palawan, resembles f. *papone*; forewing above with 2 rows of white spots besides the marginal spots; beneath there is a long white streak in the cell of the forewing and another behind the costal of the hindwing, also the median of the hindwing is sparsely margined with white to the base. — In **palephates** *Westw.* (20 c) the white scaling beneath is even more extended than in *panopinus*, especially on the hindwing; the forewing above has 3 large subapical white patches. Philippines: Luzon, Mindoro, Mindanao. — **echidna** *Bdv.* (20 d). On the islands of the Timor Group occur again *dissimilis*-like forms, which are principally distinguished from *dissimilis* by the marginal spots of the hindwing, inclusive of the anal spot, being white on both sides; also on the under surface of the hindwing the costal margin is not pure white and the white stripes surrounding the cell are narrower and shorter. In the Tring Museum 17 ♂♂, 2 ♀♀ from Timor, Wetter, Alor and Adonara. The genitalia differ somewhat from those of the preceding forms. — **echidnides** *Fruhst.* is distinguished from *echidna* by a slight shortening of the patches placed distally from the apex of the cell of the forewing. Moa; 3 ♂♂ in the Tring Museum.

flavolimbatus. *panopinus.* *palephates.* *echidna.* *echidnides.*

P. veiovis *Hew.* (= samanganus *Fruhst.*) (20 d). The lateral spots of the abdomen united into transverse bands, which are interrupted above. Markings of the wings *dissimilis*-like; ground-colour white, often yellowish, especially on the under surface of the hindwing, the veins, the cell-stripes and a broad marginal area which encloses light double stripes black; the forewing elongated, with incurved distal margin; the hindwing at the abdominal margin much longer than in *clytia*, with distinctly projecting tooth at the 3. radial and yellow anal spot. The ♀ has broader wings than the ♂. — North and South Celebes; the differences given by Fruhstorfer between northern and southern specimens are not confirmed by the 16 examples before me. The butterfly according to Fruhstorfer drinks at puddles and at the edges of brooks, the wings being kept closed.

veiovis.

P. paradoxa. Another extraordinarily variable species. Nearly allied to *clytia*, but the cell of the hindwing still narrower, especially towards the base; both wings with very small white marginal and small white submarginal spots; the latter stand in a quite regular row, which is anteriorly curved costad; the forewing has no separate subapical spot in addition to this row, as in all the forms of *P. clytia*; the hindwing slightly notched between the veins, not emarginate as in *clytia*, the lobes placed between the notches feebly projecting and broadly rounded. The genitalia are very different from those of *P. clytia*. The butterfly occurs in a number of geographical races, which all possess two principal forms. Of these two principal forms, the *paradoxa*- and the *caunus*-form, the latter in every district is fair y constant, though distinctly dimorphic sexually, whilst the *paradoxa*-form is not only everywhere strikingly different in the sexes, but in many districts exhibits a large number of individual variations both in ♂ and ♀, some of which are very dissimilar. We unite the *caunus*- and *paradoxa*-forms, which hitherto have always been regarded as 2 species, into one, on the following grounds. Whilst all the rest of the allied species are structurally different, *caunus* and *paradoxa* are identical in this respect. This has so much the more weight, because even the geographical races of *P. clytia* and also of *P. paradoxa* (inclusive of *caunus*) differ somewhat in the genitalia. Further this geographical variation in the genitalia in *caunus* and *paradoxa* is exactly the same, i. e. the *caunus* coming from a certain locality shows in the genitalia the same difference from the other geographical races as the *paradoxa* from the same district. Now as a similar strong dimorphism is known of *P. clytia*, we entertain no further doubt that *caunus* and *paradoxa* are one and the same species. A *proof* can naturally only be obtained by breeding. The larva of the *paradoxa*-form is known, but quite insufficiently described: it is velvety black or green, with fleshy spines and round red lateral spots; the large light patches of the *clytia*-larva do not seem to be present in *paradoxa*. Pupa as in the allied species resembling a broken-off twig, green or brown according to the colour of the twig on which it is fastened. The butterfly is rare, especially the *caunus*-forms; the ♂♂ are taken in woods at puddles on roads. The butterflies so closely resemble the Euploeids which they mimic that when flying they are not recognised as Papilios until on scenting danger they abandon the slow Euploeid flight and hasten away with great speed like a true Swallowtail. Distributed from North India to Palawan and Java; commonest on Borneo. The species represents on the large Sunda Islands the missing *P. clytia*, of which it was apparently a geographical race, which has now developed into an independent species. — The largest race occurs in Assam, Tonkin, Borneo and Tenasserim: **telearchus** *Hew.* Forewing above in the ♂ of f. **telearchus** *Hew.* (32 a) glossy blue, a spot in the apex of the cell, a row of elongate discal spots and the submarginal spots white-blue, the latter almost white; the dark brown upper surface of the hindwing and the paler brown under surface of both wings with white submarginal spots.

telearchus.

In the ♀ both wings with white-grey stripes in addition to the spots of the ♂, the distal half of the forewing
danisepa. purple-blue, the patches less blue than in the ♂. The *caunus*-form is f. **danisepa** *Btlr.* (32 b); the forewing of the ♂ above glossy blue, with a large white patch in the apex of the cell and smaller patches on the disc; hindwing from the base to beyond the apex of the cell white, this area divided by the black veins and distally suffused
aenigma. with blue. The ♀ is very similar to the ♂, larger. — **aenigma** *Wall.*, from the Malay Peninsula, Penang, Singapore, East and West Sumatra and Banka. The ♂ of the *paradoxa*-form occurs in two variaties: ♂-f. **aenigma** *Wall.* (= distanti *Rothsch.*, butleri *Dist.* not *Jans.*) has on the forewing light blue discal stripes on a glossy blue ground and a row of white submarginal spots, often shaded with blue, and a light blue spot in the cell. Of
butleri. the second form, ♂-f. **butleri** *Jans.*, only the type (in the Tring Museum) is known to me. The specimen bears the locality-label „E. Indies (? Malacca)", its origin is therefore doubtful. The forewing is velvety black, without blue gloss, a spot in the cell and a row of narrow discal stripes dark blue, the distal ends of the stripes slightly whitish, corresponding to the white submarginal spots of the under surface. The ♀ of the *paradoxa*-form in three
penomimus. varieties: ♀-f. **penomimus** *Mart.* (= fuscus *Hag.* not *Goeze*). Forewing dark brown, without blue gloss, posteriorly on the disc usually somewhat lighter, the submarginal spots weakly developed, the anterior ones above and beneath effaced; the hindwing without or with long, light discal arrow-spots, always with rather large, strongly
nepticula. curved submarginal spots. ♀-f. **nepticula** *Rothsch.* has likewise no blue gloss on the forewing, the latter bears between the apex of the cell and the distal margin 5 or 6 white stripes and in the cell a white spot; the hindwing
haasei. brown, with white submarginal spots. In ♀-f. **haasei** *Rothsch.* both wings are striped with white from the base above and beneath; the forewing more or less broadly glossy blue between the large white submarginal dots and
aegialus. the apex of the cell, a white dot in the cell. The *caunus*-form of the same districts is f. **aegialus** *Dist.* (= velutinus *Bllr.*): only the ♂ known; smaller than f. *danisepa*, the two white stripes placed before the cell of the hindwing are more indistinct and sometimes entirely absent. This form is considerably rarer than *aenigma*. — On
telesicles. Borneo the species varies quite in the same way as on Sumatra and Malacca: **telesicles** *Fldr.* The ♂ of the *paradoxa*-form is found in two principal types: the commoner is ♂-f. **telesicles** *Fldr.* (= kerosa *Btlr.*, juda *Btlr.*, zanoa *Btlr.*) (20 b), with light blue discal stripes on the forewing; not constantly different from *aenigma*, the light blue stripes in general thinner and less numerous. In the second form of the ♂ the forewing with the exception of the base is also glossy blue, but the light blue stripes are entirely absent, and the submarginal
eucyana. spots of the forewing above are wanting or only the anterior ones are present: ♂-f. **eucyana** *form. nov.* (from
leucothoides. South-East and North Borneo, in the Tring Museum). The ♀ in 4 principal varieties: ♀-f. **leucothoides** *Honr.* (= schoenbergianus *Honr.* ♀ not ♂) (32 b); both wings brown, between the veins more or less pale brown, without blue gloss, the submarginal spots of the hindwing smaller and placed further from the distal margin than in ♀-f.
russus. *penominus* from Sumatra. ♀-f. **russus** *Rothsch.* (32 b) is likewise brown; the forewing has large white subapical stripes and sometimes glossy blue scales at the apex of the cell, the submarginal spots are smaller than in ♀-f.
daja. *nepticula* from Sumatra and Malacca. ♀-f. **daja** *Rothsch.* corresponds to ♀-f. *haasei*, but the white stripes of the hindwing are shorter and, at least on the upper surface, not forked distally; the forewing is more extended blue. A fourth form, which is not yet known from the preceding localities, has no blue gloss on the forewing and both
albostriatus. wings bear a complete row of white discal stripes: ♀-f. **albostriatus** *Rothsch.* (32 c); the cell of both wings is striped with white, especially beneath, and that of the forewing has a white apical spot. The *caunus*-form of these
mendax. districts is f. **mendax** *Rothsch.* (= typhrestus *Fruhst.*). The ♂ is very similar to f. *aegialus*, but the white of the hindwing is more strongly reduced. The ♀ of *mendax* differs from its ♂ much more than the *danisepa*-♀ ab; much paler than the ♂ and the white basal area of the hindwing larger, the stripes placed before the cell being present. We know *mendax* from North and South-East Borneo, *albostriatus* and *russus* from North Borneo
melanostoma. and *daja* as well as *leucothoides* from North and South-East Borneo and the Natuna Islands. — **melanostoma** *subsp. nov.*; 1 ♂ from Palawan (J. Waterstradt coll.) in the Tring Museum. Forewing broad, with the exception of the base glossy blue, with very slight traces of light blue discal stripes; no spot in the cell, the submarginal spots blue-white, not sharply prominent, the anterior 4 almost effaced, the posterior 4 somewhat more distinct; hindwing with whitish blue submarginal spots, which are placed in purple wedge-shaped patches. Under surface distally paler than in Borneo specimens, the submarginal spots brownish, consequently less prominent
niasicus. than in *telesicles* and *aenigma*. Palpi black, with scattered white scales. — **niasicus** *Rothsch.* ♂: forewing with white submarginal spots, of which the anterior ones are larger than in the other races, without distinct pale blue discal stripes. Only one ♀-form known: without blue gloss, on the forewing a cell-spot, a row of discal stripes and submarginal spots white; hindwing only with submarginal spots. Nias. A *caunus*-form is not known from
mesades. there. — From the Batu Islands Lathy figures as *aegialus* the ♀ of a *caunus*-form which Fruhstorfer calls **mesades**; as no ♀ is yet known of *aegialus* it remains to be proved whether *mesades* really differs from *aegialus*. According to the figure the forewing is without blue sheen and the white markings of both wings are larger than in Borneo
paradoxa. specimens. — **paradoxa** *Zink.* (20 b) flies on Java. In f. *paradoxa* the forewing is glossy blue and has a complete row of pale blue discal stripes, some of which are white in the centre; the bluish white cell-spot and the submarginal spots large, beneath there are always white discal diffuse spots on the forewing, sometimes a complete row. The ♀ is lighter or darker brown; the hindwing above and beneath with white discal arrow-spots, which are placed at a distance from the cell, and white submarginal spots; the arrow-shaped markings are indistinct
caunus. in dark specimens. Striped ♀♀ are not known to me from Java. There also occurs on Java f. **caunus** *Westw.*

which, however, is much rarer than *paradoxa*; only the ♂ known: the submarginal spots of both wings larger than in *aegialus* and *mendax*; the white stripes of the hindwing narrow, recalling the ♀ of *mendax*, two of these stripes before the cell.

Castor Group.

Forewing on the 2. discocellular with a white dot, which is sometimes only developed beneath. Both sexes or only the ♀ Euploea-like, entirely without blue gloss. Tailless, but often with a distinctly projecting tooth at the 3. radial; the upper surface of both wings, and beneath the apex of the cell of the forewing and the whole of the hindwing more or less thickly dusted with yellowish scales; ground-colour black or blackish brown, all the markings white, at most the anal part of the hindwing distinctly yellow; the white subdorsal dots of the abdomen always present; the marginal spots of the hindwing thinner than those of the forewing. The larva as in *P. polytes* with oblique bands, when full-grown entirely without the rows of spines of the *clytia* and *agestor* groups; the pupa also not almost cylindrical as in these, but broad in the middle, with the anterior part rather strongly curved upwards. A connecting link between *clytia* on the one side and *canopus*, *helenus*, *polytes*, *pitmani*, etc., on the other.

P. dravidarum *Wood-Mas.* (= abrisa *Kirby*) (31 d). Forewing with a row of large, yellowish white submarginal spots. Hindwing with a complete row of discal and submarginal spots; the discal patches remote from the cell, proximally pointed, distally emarginate, the submarginal spots lunular. The ♀ quite similar to the ♂. The larva with a pair of small humps on each of the last two segments, the segment-incisions blue, with the exception of the 4. and 5. segments, where they are black; thorax with a spectacle-like band, all the segments except the first with 2 blue dots at each side, abdomen with 2 oblique green bands, which are only slightly prominent, above the legs a white longitudinal stripe. Horns on the head of the pupa strongly produced, the wing-cases projecting. Food-plant: Glycosmis pentaphylla. — South-India: Travancore, Mysore, Nilghiri Hills, etc. At lower elevations in the hills, the ♂ rather common. At the end of the rainy season near the evergreen jungle; during the cold season the butterfly is often met with in the beds of rivers, where it flies up and down and quite gives the impression of a *Euploea*. *dravidarum.*

P. castor. Forewing in the ♂ without submarginal spots or these quite small. The ♀ paler than the ♂, the submarginal spots of the forewing likewise small, or the anterior ones much larger than the posterior. — **polias** *subsp. nov.* differs from the nymotypical form from Assam only in the ♀. The forewing of the ♀ bears beneath and often also on the upper surface diffuse grey spots from the lower angle of the cell to the hindmargin; the hindwing is for the most part occupied by broad, diffuse grey streaks, which above extend almost, and beneath quite to the base, so that also the cell at least beneath is entirely filled up with grey. The ♂ brownish black with 4 large yellowish white discal patches on the hindwing above, the marginal tooth of the 3. radial distinctly projecting. Sikkim, all through the summer in lower elevations, up to about 3000 ft.; Burma. — **castor** *Westw.* (♀ = pollux *Westw.*) (29 c). The ♂ appears not to differ from specimens from Sikkim. Examples occur, among normal ♂♂, in which the hindwing has a complete row of white submarginal spots on both surfaces, and sometimes in such specimens there are 5 discal spots and traces of a 6. and 7. spot on the upperside. The Tring Museum possesses 2 such ♂♂ from Cherrapunji (Assam); they connect *castor* with *mehala*: ♂-ab. **mesites** *ab. nov.* In the ♀ the hindwing is much less extended grey than in the Sikkim form; the cell is either entirely brown or only indistinctly grey at the apex; on the disc a broad band of large grey or yellowish white patches, which mostly are also rather sharply defined proximally. Assam. — **dioscurus** *subsp. nov.* Only 4 ♂♂ known to me: The band of the hindwing above and beneath consists of three or four patches, which are smaller than in the two preceding forms; the 2. and 3. patches only as long as, or shorter than their distance from the distal margin. Than Moi, Tonkin (H. Fruhstorfer). — **mehala** *Grose-Smith.* ♂ without distinctly projecting tooth at the 3. radial of the hindwing; the submarginal spots of this wing well developed also above; the 2.—4. discal patches larger than the following ones, the latter often absent. ♀ on the forewing with a complete row of submarginal spots, of which the anterior ones are the largest; on the hindwing a row of grey, somewhat diffuse discal patches and a row of large white submarginal lunules. Lower Burma and the adjoining districts of Tenasserim. — **mahadeva** *Moore* (= maheswara *Fruhst.*) (31 d). ♂: the hindwing always with a complete row of discal patches, of which the anterior ones are less enlarged than in *mehala* and *castor*, the submarginal spots likewise all developed. The ♀ marked similarly to the ♂, on the forewing the discocellular spot and the submarginal spots larger, on the hindwing the discal spots shaded with brown. Upper Tenasserim, Shan States, Siam and the east side of the Malay Peninsula. Very similar to *P. dravidarum*, but easy to distinguish by the small submarginal spots of the forewing. — Fruhstorfer has described as **phanrangensis** a specimen (♀) from South Annam, which is „sufficiently characterised by the more rounded wings, the small size and the reduced macular bands of the hindwing". The discal band of the hindwing almost effaced. Unknown to me in nature. — In the Museum at Singapore are 2 specimens from Selangore which have no submarginal spots *polias.* *castor.* *mesites.* *dioscurus.* *mehala.* *mahadeva.* *phanrangensis.*

selangoranus. on the upperside of the hindwing and have been named **selangoranus** by FRUHSTORFER. — **hamela** *Crowl.*, *hamela.* from Hainan, has in the ♂ no submarginal spots on the hindwing above, the discal band is formed as in *mahadeva*, but the distal margin has a distinctly projecting tooth at the 3. radial. The brown ♀, of which there is a specimen in the Tring Museum, has on the forewing as in *mehala* a row of submarginal spots, of which the anterior ones are the largest; on the hindwing the discal spots are almost entirely absent above *formosanus.* and beneath and the submarginal spots are small. — In **formosanus** *Rothsch.* (= gotonis *Mats.*) the sexes are similar. The ♂ agrees to a great extent with the *castor*-♂; on the upper surface of the hindwing are 4 yellowish white patches, which are smaller than in *castor*, the submarginal spots are wanting above, and only the anterior ones are developed beneath. In the paler ♀ the hindwing usually has small submarginal spots and between the large discal patches and the abdominal margin 3 more spots are indicated. Both sexes have a distinctly projecting tooth at the 3. radial. Formosa, in the hills. — The larva of *P. castor* is not yet known. The butterflies drink on moist sand and come after the refuse from the houses of the settlers. When frightened away they soon come back again. Their flight is low and feeble.

If a linear arrangement according to relationship were possible we should continue with *P. canopus*.

We insert here some Papuan forms which are mimics of Uranids and Acracids.

Laglaizei Group.

Upper surface of the wings blue-black, with grey-blue median band and on the forewing in addition a narrow grey-blue subapical band, the bands not metallic; the short-tailed hindwing beneath with orange-coloured patch behind the base of the lower median. The subcostal and lower median of the hindwing branching off far from the base, much as in the *agestor* group; antennae short as in that group; the genitalia likewise recall the *agestor* group.

laglaizei. **P. laglaizei** *Depuis.* (= alcidinus *Btlr.*) (38 c). ♂♀: the median band of both wings broad, the tail and usually also the adjoining part of the distal margin grey-blue; the under surface for the most part blue-grey, the hindwing in fresh specimens bluish grey with a faint yellowish tone. The individual markings very variable in specimens from the same district; the black spots on the disc of the hindwing beneath often much enlarged and the proximal patches confluent with the corresponding distal ones. A ♂ from Astrolabe Bay with narrow blue instead of blue-grey median band and blue under surface was described *wahnesi.* by RÖBER as a distinct species; I consider the specimen an aberration: ab. **wahnesi** *Röb.* — The area of distribution of *laglaizei* embraces the Aru Islands, Waigeu and the whole of New Guinea. The butterfly is in general rare, yet the Tring Museum once obtained a collection from Dutch New Guinea, made by natives or Malays, which contained about 100 specimens of this species. According to A. S. MEEK *laglaizei* is also no rarity at the south-east extremity of British New Guinea, not even at the coast. The resemblance to *Alcidis agathyrsus* is surprisingly faithful on the upper surface; the under surface differs considerably from that of the model, but bears a usually very conspicuous orange spot which corresponds to the orange-coloured underside of the abdomen of *Alcidis*. The two butterflies fly together round the tops of trees, but the Uranid is much commoner than the Papilio. C. WAHNES has bred the butterfly more than once and has sent several blown larvae to the Tring Museum. These are black; on each segment a broad yellowish red girth, in which as well as in the black belts light yellow dots are placed; at each side of the back a row of short black spines, which are placed on large round black dots, at the dorsal side of which is a yellow dot; the last segment for the most part black; head black; scent-fork (in the inflated specimens) yellowish grey. Foodplant not recorded, probably Citrus. Herr RIBBE, without giving any characterisation (!), has proposed the names *mukaensis* for specimens from Waigeu and *maraganus* for the „New Guinea form"; such *nomina nuda* have naturally no right of priority, should the specimens from the localities mentioned really be different and therefore have to be named.

toboroi. **P. toboroi** *Ribbe* (38 c). Whilst in *laglaizei* almost the whole upper surface of the body and also the sides of the abdomen are blue-grey, *toboroi* has an entirely black body without any markings. Upper surface of the wings dark blue, with a slight oily gloss; the median band of both wings narrow, the part placed in the cell of the forewing is commonly diffuse and is always at a distance from the apex of the cell; on the hindwing a pale yellow anal spot, the tail entirely black-blue. The under surface in contrast to *laglaizei* for the most part black; in the forewing a submarginal band, which is anteriorly broad and greyish yellow, posteriorly narrow and bluish, and before the middle a more or less indistinct narrow blue band; on the hindwing a large basal area and a broad submarginal band are grey-yellow, and the black central area is more or less broken up into large patches, the orange-coloured spot before the hindmargin paler than in *laglaizei*. The ♀ as in *laglaizei* quite similar to the ♂; on the upper surface of the hindwing it has from the 3. radial backwards an irregular narrow grey-blue submarginal band, which in the ♂ is only indicated. — Bougainville,

Solomon Islands; in the interior of the island, a few miles from the coast, the butterfly is rather common in low situations. An *Alcidis* similar to *toboroi* does not appear to occur on Bougainville, on the other hand MEEK sent a series of a species of *Dysphania* which, in spite of its smaller size, bears quite the same aspect as the *Papilio. toboroi* differs from *laglaizei* in neuration and in the genitalia as well as in the markings.

Anactus Group.

Palpi and forecoxae orange, the posterior segments of the abdomen (except the anal claspers) pale yellow; cell of the forewing with grey-white apical spot and larger patch in the middle. — A mimetic offshoot from the next group.

P. anactus *Mac Leay* (24 c). Body black, with pale yellow spots, the last segments of the abdomen *anactus.*
almost entirely pale yellow. Forewing elongated, with very long cell, brown-black, a large patch in the middle of the cell, a smaller one at its apex and a band of large discal patches white, dusted with blackish, a row of rounded submarginal spots white. The hindwing darker than the forewing, with large white central area, which extends from the costal margin to the hindmargin and encloses a black discocellular lunule; the submarginal spots red, distally to the white area some blue spots. Under surface as upper. The ♀ quite similar to the ♂. The larva on Citrus, in the earlier stages resembling bird-droppings, with 2 rows of long processes bearing spines, on the thorax in addition 2 shorter humps. When full-grown black, with 3 rows of pale yellow patches, one on the back and one at each side, the lateral patches of the 4. segment small; 2 rows of black spikes, laterally from which on the meso- and metathorax another black hump is placed; scent-fork orange. Pupa almost cylindrical, with scarcely projecting wing-cases, the horns of the head strongly produced, on the innerside with two tubercles, the thoracic horn short, on the back 2 rows of small humps. The butterfly resembles *Acraea andromache* on the wing; in cultivated districts, where Citrus grows in the gardens, in several broods from October to March; the larva is also sometimes found on Ruta, but prefers the imported species of Citrus to all the indigenous plants. — North Queensland to New South Wales.

2. Non-mimetic Forms and Mimics of Aristolochia Papilios.[1])

Apart from the upperside of the head and prothorax and the palpi, the body in the Indo-Australian forms has no white dots, and there are no small white spots present at the base of the wings beneath. The ♂♂ are only mimetic in a few cases (*canopus*, *booles*, *janaka*); the ♀♀ of a number of species are polymorphic (*memnon*, *polytes*, *aegeus*, etc.).

Demoleus Group.

Body beneath entirely yellow, or at most with black lines; the base of the cell of the forewing beneath striped with pale yellow; the greater part of the hindwing or at least a large central area pale yellow. — The species of this group show close affinities in various directions. Whilst *machaon* has a series of allied species in America and *demoleus* in Africa, *cuchenor* is doubtless closely related to *gigon.*

P. machaon occurs in the Indian region in three geographical forms. In the north-west of the region, from Kashmir to Nepal, occurs **asiatica** *Mén.* (vol. I, 6 b). This form has always very broad black bands *asiatica.*
and differs from dark South European *machaon*, which are *sphyrus Hbn.*, principally in that the yellow-dusted discal band of the hindwing beneath is much narrower at the 3. radial (which supports the tail) than in the European form. Very common everywhere in the north-west Himalayas, in the valleys from February to October, in the mountains not until March or April, from 2000 to 14,000 ft. The short-tailed specimens from Kashmir, which occur especially at higher elevations, are *ladakensis Moore.* The larva feeds on Umbelliferae (Daucus, Foeniculum, etc.) and is not distinguishable from European larvae. At lower and medium altitudes at least two broods. The summer butterflies are larger than those which emerge from the hibernated pupae in the spring. The name *pendjabensis Eimer* refers to small specimens of *asiatica.* — **sikki-** *sikkimensis.*
mensis *Moore* occurs at elevations in Sikkim and Bhotan, and is especially common in the adjoining districts of Tibet, i. e. on the Palaearctic territory. The black bands in both sexes very broad; the blue crescent on the anal eyespot of the hindwing is separated from the red spot by a curved black mark. The larva on Umbelliferae, still undescribed. — **verityi** *Fruhst.* (= archias *Fruhst.*, birmanicus *Rothsch.*) (32 c) flies *verityi.*
in Upper Burma, the Shan States, West Yunnan and the adjoining parts of East Tibet, and differs from *sikkimensis* chiefly in the much narrower discal band of both wings. The tail is long; the abdominal margin

[1]) Only a few forms of *P. canopus*, which leads over to the *castor* group, are mimics of Euploeids.

of the hindwing is only narrowly black, so that the area behind the cell and the 2. median remains yellow for the most part.

xuthus. **P. xuthus** *L.* (= xanthus *L.*) (vol. I, 6 a). The veins broadly black; the cell of the forewing striped with pale yellow from the base to $^2/_3$, the pale yellow stripe placed behind the cell on both wings extending to the base. This mainly Palaearctic species (for whose habits, etc., see vol. I, p. 11) extends southwards to Upper Burma and also occurs on Formosa, the Bonin Islands and Guam. The ♀♀ from Guam are very dull, the light markings being more or less distinctly dirty yellowish. — FRUHSTORFER has based upon a single *koxinga.* ♂ from Formosa the subspecies **koxinga;** the specimen is distinguished by lemon-yellow colour (discoloured?). — In the Palaearctic Region the species is very strongly horodimorphic, and this is the only case known to me where the ♂♂ genitalia of the spring form differ distinctly, though not quite constantly, from those of the summer form.

P. demoleus. The underside of the body, the sides of the head and a stripe at each side on the thorax pale yellow. Forewing above at the base dotted with pale yellow, these dots united into transverse lines; in the cell a large patch, commonly broken up into 2 spots, at the upper angle of the cell 2 or 3 spots, on the disc a macular band, the upper spots small and placed far apart, the posterior ones large and usually contiguous; this band on the hindwing not interrupted; both wings with a row of submarginal spots and small marginal lunules; all these markings pale yellow; on the hindwing between the upper submarginal spot and the median band a rounded black patch, which is ornamented with a blue crescent, at the anal angle a red spot. Beneath more extended pale yellow; forewing at the base with pale yellow longitudinal stripes, hindwing with narrow black transverse band near the base, and on the disc with 2 rows of black spots, between which the wing is more or less deep ochreous. The egg pale yellow. The young larva of the Indo-Chinese form blackish, a large V-spot in the middle, a lateral stripe from the prothorax backwards and a second stripe running from the anal segment forwards milky white; several rows of setiferous processes; the full-grown larva green, the protuberances only persisting on the 1. and last segment, on the thorax and at the base of the abdomen a yellow, black-edged belt, and behind the middle an oblique lateral band of the same colour; the nuchal fork saffron-yellow. Pupa grey or green, the horns on the head longer than they are broad at the base, the thoracic horn short, the abdominal tubercles small. Food-plants: various species of Citrus, Glycosmis, Murrayia, etc., also on herbs, e. g. Ruta angustifolia. The butterfly is very common in tropical Asia and extends westward to Muscat and Persia. Its distribution in the Indo-Australian Archipelago is very peculiar: the butterfly is still common in the Malay Peninsula, but wanting on the large Sunda Islands, the Philippines, Celebes and the Moluccas, but occurs again on the small Sunda Islands, in North Australia and Southern New Guinea. It is true that single specimens have been recorded by WALLACE from Goram, by REAKIRT from the Philippines and by FRUHSTORFER from Java, but these are evidently stray or accidentally imported specimens. From Timor no specimen is as yet known. The large gap in the region of distribution of the species is intelligible if we take into consideration the nearly allied species, *P. demolion*, *gigon* and *antonio*, which occur on the large Sunda Islands (*demolion*), Celebes (*gigon*) and the Philippines (*antonio*), where *demoleus* is wanting. Another allied species (*euchenor*) inhabits New Guinea and the Bismarck Islands. *P. demoleus* flies in the lowlands all the year round; it is found more in open country, especially in gardens, than in woods, and visits by preference the flowers of citron trees and Raphanus; also the insects commonly congregate at puddles, where they drink with closed wings. The butterfly flies *demoleus.* slowly when it thinks itself safe, but hurries off in swift, irregular flight when it scents danger. — **demoleus** *L.* (= erithonius *Cr*, epius *F.*) (vol. I, 6 d), from China, Hainan, Tonkin, North and South India, Ceylon, Persia and Muscat, is extraordinarily common in many districts. The cell of the forewing has near the apex two separated patches, the spot placed at the hindmargin of the discal band of the forewing is mostly only as long as broad, and the penultimate and antepenultimate spot of this band are usually distinctly separated. The red spot of the hindwing is sometimes also in he ♂ reduced proximally and *demoleinus.* therefore separated from the blue lunule by a black spot: ab. **demoleinus** *Oberth.* Many specimens have on the forewing above a small discal spot before the 2. radial; sometimes (especially often in specimens from Ceylon) there are two small spots on the hindwing above distally to the cell between the 1. and *malayanus.* 3. radial. — **malayanus** *Wall.* inhabits Burma, Annam, Siam and the Malay Peninsula and is distributed southwards to Singapore. The posterior 3 patches of the median band of the forewing above *annamiticus.* are broader than in the preceding form. Specimens with specially broad patches are ab. **annamiticus** *Fruhst.* Only some of the specimens obtained by FRUHSTORFER in Annam have this character. It is not a dry season form, as FRUHSTORFER surmised. Seasonal dimorphism in tropical Asia is principally observed in the butterflies of North India; but our spring and summer specimens of *demoleus* from Sikkim (MÖLLER *sthenelinus.* coll.) exhibit no differences. — **sthenelinus** *Rothsch.* (21a). The cell of the forewing has above instead of the 2 spots only a single large patch, which is broader anteriorly than posteriorly and bears a thin process directed towards the lower angle of the cell; the discal spots of the forewing smaller than in all the other subspecies. On the Lesser Sunda Islands, from Flores to Alor. Sumbawa and Lombok do

not appear to have been reached by this butterfly. — **sthenelus** *Mc. L.* (= pictus *Fruhst.*). The cell of the forewing above with a large constricted transverse patch, which is as broad posteriorly as anteriorly. The posterior discal spots of the forewing and the band of the hindwing broader than in *sthenelinus*. The young larva black, without saddle-spot; the later stages lighter; the full-grown larva green, with rows of orange dots and above the legs a white longitudinal stripe, the abdominal legs whitish. On Citrus and other plants. The butterfly in open country, especially in lucerne and clover fields; North-West Australia, Queensland, southwards to Sydney; the specimens from the islands in the Torres Straits probably belong here. This form is also common on Sumba Island, to the south of Flores; specimens from there cannot be distinguished from Australian ones. Fruhstorfer gave them a name, erroneously comparing them with *sthenelinus* instead of *sthenelus*. The Sumba Lepidoptera are usually very specialised; it may therefore be assumed that *sthenelus* has only recently immigrated there. — **novoguineensis** *Rothsch.* Very similar to the preceding form; the cell-patch of the forewing more deeply incised, the posterior discal spots smaller, the penultimate more deeply incised distally and anteriorly very distinctly sinuous; the black markings on the underside of the hindwing larger and the basal area shaded with yellow at the black transverse band. Mathew found egg and larva on Salvia, both similar to those of *sthenelus*, the nuchal fork of the larva salmon-coloured. The butterfly on bare slopes on the south coast of British New Guinea: Port Moresby, Redscar Bay, lower course of the Aroa River.

sthenelus.

novoguineensis.

P. euchenor. Body beneath pale yellow. ♂: forewing above with a large spot at the apex of the cell, to which is joined a discal band consisting of 5 large spots, often a few small spots distally to the end of the cell, a subapical band of at least three small spots; hindwing with very large central area which extends from the costal almost to the hindmargin, is cut off straight basally and irregularly rounded off distally and incised at the veins; all these markings pale yellow. Under surface as upper, but the subapical band of the forewing consisting of more spots, the central area of the hindwing extended to the base, and distally to it a row of submarginal lunules, of which the posterior ones and mostly also the costal one are ochreous yellow. In the ♀ the markings are paler and the discal spots of the forewing are reduced, the last but one commonly entirely absent. The larva, which was found by Wahnes on Citrus, rests on the upperside of a leaf; similar to that of *P. gigon*; green, with broad black lateral stripe above the legs from the prothorax to the 1. or 2. proleg, a broad belt on the 3. and 4. segment, which is broadly united with the lateral stripe, from the middle of the body onwards the brown lateral stripe replaced by an almost white one, from which three other brown, oblique belts project upwards; on the pronotum two long, feebly clubbed processes, resembling the horns of a slug, in each of the three abdominal belts a couple of long pointed processes. The pupa green, head and breast very strongly curved upwards, the thoracic horn very short. The genitalia of the butterfly recall those of *P. demolion*. The butterfly is found in light, sunny woods, especially at watercourses, and has a swift and agile flight. A true Papuan species, whose area of distribution embraces the Key and Aru Islands, the whole of New Guinea together with the small neighbouring islands, and the Bismarck Archipelago. From Australia, the Solomon Islands and the Moluccas the butterfly is not known. It is true Pagenstecher reports it from the North Moluccas, but the collection of Lepidoptera in question was bought there and the locality is therefore not authentic. — **naucles** *Rothsch.*, from the Key Islands. ♂: the cell-spot of the forewing above reaches to the base of the 1. median or still further basad, there is no black spot before the base of that vein. ♀: the 1. and 2. discal spots of the forewing are not separated, as the vein placed between them is not black, the 3. discal spot widely separated from the 2., the 4. scarcely indicated, the 5, (placed at the hindmargin) elongate-triangular; the 1. and 2. projections of the central area of the hindwing above only feebly constricted. — **obsolescens** *Rothsch.* ♂: the cell-spot of the forewing above does not reach the point of origin of the 1. median, the 2. and 3. discal spots strongly rounded off basally. ♀: as *naucles*, the cell-spot of the forewing posteriorly somewhat shorter, the 1. and 2. discal spots separated by a usually very distinct vein-streak; the two anterior projections of the central area of the hindwing above more or less strongly constricted, commonly so strongly that two spots are separated from the central area; the penultimate discal spot of the forewing not indicated either beneath or above. Aru Islands. Not rare, principally in half-dry brooks. — **misolensis** *Rothsch.* Small, the blue spots wanting on the underside of the hindwing, only the last spot is always (?) indicated by a few blue scales. Misol, 4 ♂♂ in the Tring Museum, taken by H. Kühn in January 1898. — **euchenor** *Guér.* (= axion *Bdv.*, lasos *Fruhst.*, scribonius *Fruhst.*, hippotas *Fruhst.*) (26 a). ♂: the subapical spots of the forewing smaller on both sides than in *naucles* and *obsolescens*, the 2. discal spot not rounded off basally; the submarginal spots of the forewing beneath small or not present, the hindwing always with blue spots. ♀: the 3. discal spot of the forewing above a ways placed near to the 2., mostly touching it, the 4. spot always present, the interspace between the 4. and 5. spots not broader than the latter; the yellow submarginal spots of the hindwing beneath very variable, the posterior ones commonly united into rings with the marginal spots, which is also sometimes the case in the ♂. The subapical spots of the forewing in both sexes from German and British New Guinea mostly larger than in the specimens from the Arfak Peninsula, but also sometimes smaller. In specimens from Waigeu the marginal spots of the hindwing are rather small and the inner margin of the pale yellow area of the hindwing above usually crosses the cell at the point of origin of the 2. median, which, however, often occurs

naucles.

obsolescens.

misolensis.

euchenor.

also in specimens from other districts. Distributed over the whole of New Guinea; Waigeu, Salawatti (1 specimen in coll. FELDER, is the locality correct?), Dampier. — **eutropius** *Jans.*, from Jobi. The cell-spot of the forewing in ♂ and ♀ smaller than in New Guinea specimens, the 3 subapical spots enlarged, the 3. in the type (♂) united with a spot placed distally to the cell into a hatchet-shaped patch, in normal ♂♂ (ab. **mago** *Fruhst.*) on the contrary these spots not united; in the ♀ the 2. subapical spot triangular and the 3. linear, both much enlarged on the under surface, the 4. discal spot of the ♀ smaller than in *euchenor*, above not as broad as the interspace which separates it from the 3. spot, the latter not connected with the 2. The differences are probably not constant; only 1 ♂ (the type) and 1 ♀ are known to me in nature. — **godarti** *Montr.* (= intercastellanus *Rothsch.*, euchenides *Fruhst.*). The subapical spots of the forewing above large, beneath touching one another, the submarginal spots following them also mostly larger than in *cuchenor*. In the ♀ in addition the three anterior discal spots of the forewing separated, or the 1. and 2. touching for a short distance, the base of the 3. radial remaining black. D'Entrecasteaux Islands (Fergusson, Goodenough, Trobriand) and Woodlark. — **rosselanus** *Rothsch.* ♂: the forewing above with 1 or 2 submarginal spots below the subapical row of 3 spots, the 3. subapical spot broadest posteriorly, hook-shaped, the 2. large discal spot about twice as long as its distance from the margin; on the upperside of the hindwing before the subcostal, distally to the pale yellow area, is placed an oblique pale yellow streak, which corresponds to the yellow submarginal patch on the underside; this latter mark very oblique, shaped almost like the figure 3, posteriorly at the subcostal united with the yellow area or at least very close to it. The ♀ not known. 6 ♂♂ from Rossel, Louisiade Islands, in the Tring Museum. — **sudestensis** *Rothsch.* Very similar to the preceding subspecies, the 1. subapical spot of the forewing broader, the oblique subcostal streak placed distally to the yellow area of the hindwing above only indicated, removed further from the yellow area, the corresponding spot on the under surface less oblique than in *rosselanus*, before the subcostal separated from the yellow area by a black interspace at least 2 mm broad. The 3. subapical spot of the forewing above broadest posteriorly, but mostly not hook-shaped; beneath it there is usually a small submarginal spot. The ♀ not known. Sudest, Louisiades; 4 ♂♂ in the Tring Museum. — **misimanus** *Rothsch.* occurs on St. Aignan, Louisiades. ♂: the 1. subapical spot of the forewing above only a little longer than broad, the 3. as long as broad, sometimes somewhat broader than long or again somewhat longer than broad, at the innerside more or less emarginate, beneath this spot a submarginal spot, the veins between the discal patches black, the 2. discal patch not quite reaching the cell before the 1. median, the last discal patch not produced further distally than the 4., on the hindwing usually a very small subcostal streak distally to the yellow area. On the forewing beneath the subapical spots usually touching one another and forming with the two large submarginal spots which follow them an almost uniformly curved macular band; the rounded black subcostal spot of the hindwing much broader at the subcostal than in the two preceding forms. The ♀ further distinguished by the strong reduction of the discal spots of the forewing, the 1. and 2. spot separated, the 3. small, far removed from the 2., sometimes only indicated, the 4. absent or dot-like, the 5. narrow, not touching the submedian vein. All the preceding forms of *P. euchenor* possess in the ♂ scent-scales on the veins of the forewing above, the genitalia are also very similar, although differences can be made out in the various subspecies.[1]) The three following geographical races on the contrary have no scent-stripes and the genitalia, although of the same type as in the other forms, are strikingly different from those of these races. — **depilis** *Rothsch.* The discal band of both wings in the ♂ broader than in the preceding forms, the 4. and 5. discal spots extending nearer to the margin, the veins inside the band not black; the part of the yellow area of the hindwing placed behind the subcostal not constricted; on the under surface the margins of the cell-patch and of the discal patches of the forewing more or less diffuse, the black subcostal spot of the hindwing transverse. ♀: forewing with five discal spots, contiguous or only separated by narrow black veins, the yellow area of the hindwing above not extending basad to the points of origin of the subcostal and 2. median veins, the black subcostal patch of the hindwing beneath transverse as in the ♂, and the discal spots of the forewing beneath broadly contiguous with one another and with the cell-spot New Pomerania (= New Britain); New Lauenburg (= Duke of York). — **novohibernicus** *Rothsch.* Before the apex of the cell of the forewing above in ♂ and ♀ there is a small yellow spot, the yellow area of the hindwing is more deeply incised at the veins than in *depilis*, on the under surface of the hindwing the black subcostal spot is rounded off proximally and distally, and the submarginal lunule placed behind the 2. radial is further removed from the yellow area than in *depilis*. In the ♀ all the discal spots of the forewing are broadly contiguous also above. New Mecklenburg (= New Ireland). — **neohannoveranus** *Rothsch.* The three subapical spots of the forewing in ♂ and ♀ more rounded and the marginal spots of both wings larger above and beneath than in the two preceding forms, moreover the 2. section of the yellow area of the hindwing distally cut off straight or only feebly emarginate, the 3. section rather strongly constricted, the last section of the band of the forewing little if at all more produced distally than the one before it; the yellow area of the forewing still more strongly notched than in *novohibernicus*; the black subcostal spot of the hindwing beneath somewhat less rounded than in that subspecies. In the ♀ all the discal spots of the forewing above separated by the brown-black veins, the 4. spot rounded. New Hanover.

cutropius. *mago.* *godarti.* *rosselanus.* *sudestensis.* *misimanus.* *depilis.* *novohibernicus.* *neohannoveranus.*

---

[1]) See JORDAN, Mechanical Selection, in Nov. Zool. III, p. 469 (1896).

Helenus Group.

Almost always tailed. The sexes similar. Body black, with white dots on head and pronotum and thin white lines on the underside of the abdomen, these white markings often absent, in the ♀ the abdomen sometimes yellow above and black beneath. Forewing of the ♂ black, usually with white transverse or oblique band, hindwing likewise black, with white, rarely greyish blue discal area or band.

These species are not mimetic, with the exception of the forms of *P. eanopus*, which resemble Euploeids of the same districts.

P. liomedon *Moore* (21 a). Very similar to the following species, but the genitalia so different that we are undoubtedly dealing with two forms which have already become independent of one another, hence species. The patches of the band of the forewing all more or less separated; the band of the hindwing placed so far distad that it contains the apex of the cell. The ♀ similar to the ♂, less deep black, the anal ring of the hindwing reddish. Eggs laid in small clusters. Larva resting gregariously on the upperside of a leaf; the young larva oily green, with short spines, which later disappear; the full-grown larva immediately after the last moult bluish, gradually assuming a green colour; on the prothorax and the 8. and 11. segments a pair of tubercles; markings almost as in the *demoleus*-larva: four white, brownish-spotted belts run from the longitudinal stripe of the same colour, which is placed above the legs, transversely across the body, in addition on the thorax a laterally shortened belt of like colour; on Rutaceae (Acronychia laurifolia and Evodia roxburghiana). The pupa has a very long thoracic horn, curved backwards. The butterfly is not rare, but local; it flies in the wooded hills, but also in the plains. South India. — FELDER mentions *P. demolion* from Ceylon, which is probably due to an error. *liomedon.*

P. demolion. The posterior spots of the band of the forewing always contiguous; the apex of the cell of the hindwing black, placed outside the band. The ♀, as in *liomedon*, very similar to the ♂, the anal ring of the hindwing more red. The harpe of the ♂ is almost linear and bears towards the base and at the tip a long spine-like process; in *liomedon* on the contrary the harpe is broad and flat, dentate at the margin, without pointed processes. The genital armature of the ♀ consists principally of two dentate, pointed, triangular chitinous lobes, each of which is placed laterally behind the vaginal opening; in *liomedon*, although these processes are dentate, they are not sharply pointed but rounded off. Larva and pupa quite similar to those of *liomedon*; food-plant: Citrus. The butterfly, whose flight is swift and restless, visits flowers, before which it hovers with a fluttering motion of the wings as it sucks the honey; in wooded country. Occurs from Burma to Lombok and Palawan. — **delostenus** *Rothsch.*, from Palawan. Less deep black than the other subspecies. The bands of both wings narrow, on the hindwing somewhat narrower than the cell is broad, on the forewing the posterior spots contiguous, but the incisions between them deeper than in the following subspecies. Beneath the veins of the hindwing between the black discal spots yellow. — **energetes** *Fruhst.* The band of the hindwing, especially in the ♀, a little narrower than in *demolion*, not otherwise different from the latter. Nias. — **demolion** *Cr.* (= cresphontes *F.*, messius *Fruhst.*) (21 a). The band of the hindwing broader than the cell is wide. Distributed from Tenasserim and Siam over Malacca, Sumatra, Java, Banka to Lombok and North Borneo. *delostenus.* *energetes.* *demolion.*

P. gigon. Sexes similar, the ♀ paler than the ♂. Much larger than *P. demolion*, the costal margin of the forewing as in many Celebes butterflies strongly curved, the cell correspondingly strongly widened; also the cell of the hindwing differently formed from that of *demolion*, the subcostal arising much further distally than in that species, the band of the hindwing placed basally to the subcostal, cell of the hindwing beneath margined with yellow at the apex; in the genitalia nearest to *P. liomedon*. The young larva olive-green, prothorax and anal segment each with a pair of long tubercles, above the legs from the head to the anus a white stripe at each side, in the middle of the body a broad, dentate, white transverse band, which is joined to the lateral stripes. The full-grown larva blue-green, on the 3. segment a black transverse band, at the hindmargin of the 4. segment a transverse band which is light brown above, a third transverse band on the 7. and 8. segments, and a triangular lateral spot on the 9. segment; the first band in a larva observed by KÜHN on the island of Bangkai spectacle-shaped, dark brown. Pupa light grass-green, with long, curved thoracic horn; a lateral stripe from the horn to the anal extremity brown, a central stripe of the same colour on the back. Food-plant: „a wild, bush-like Aurantiaceae, probably Limonia angulosa W. & A.“; on Bangkai the larva was „found on a narrow-leaved forest tree“ (H. KÜHN). Celebes and the Siao, Talaut and Sulla Islands; not known from Salayer. — **gigon** *Fldr.* (= cresphontes *Bdv.* nec *Cr.*) (21 a). On the under surface of the hindwing the first black distal mark is about as broad at the costa as the yellowish white band, and the yellow margining of the apex of the cell is usually narrow and always produced in points at the veins. The whole of Celebes; whether the specimens from Siao and Bangkai agree with those from Celebes is not known to me. Common; its flight very rapid. — **neriotes** *Rothsch.*, from Talaut and Sangir. The submarginal spots of the forewing beneath confluent, which sometimes also occurs *gigon.* *neriotes.*

in *gigon*, in which case, however, the veins of this band are more broadly dusted with white-yellow towards
mangolinus. the base than in *neriodes*; the marginal spots of the hindwing beneath larger in both sexes than in *gigon*. — **mangolinus** *Fruhst.* On the under surface of the hindwing the yellow margining of the cell always broad and the first black discal patch smaller than in *gigon* and *neriotes*; Sulla Islands: Mangola and Besi.

antonio. **P. antonio** *Hew.* (21 b) is only known from Mindanao, and the butterfly seems to be rarely observed. Forewing above at the hindmargin with triangular white area, which forms the continuation of a large white area of the hindwing; both areas also present beneath. The hindwing beneath with a continuous row of pale yellow submarginal spots, the posterior spots more ochreous. The ♀ quite similar to the ♂, the white areas somewhat larger. — Nothing is known as to the habits and the earlier stages.

noblei. **P. noblei** *Nicév.* (= henricus *Oberth.*) (21 b). Very similar to the preceding species, but the genitalia quite different. The white spot at the hindmargin of the forewing small, the white area of the hindwing likewise smaller than in *P. antonio*, only reaching the 2. radial, the costal part of the area especially much narrower than in *antonio*. The submarginal spots of the hindwing beneath lunular, dark ochre-colour. The body beneath more extended pale yellowish than in *antonio*. — Upper and Lower Burma, Upper Tenasserim, Central Tonkin. The ♂♂ rest on the moist sand of the shady banks of rivers; they are very shy and fly up at the least noise, disappearing high above the tree-tops, whence they only return after half an hour or an hour. The ♀♀ were only taken on Lantana-bushes.

P. nephelus. Similar to *chaon* and *helenus*. Palpi laterally quite white. Forewing with white marginal dots, of which the one placed at the apex is the largest; the ♂ without scent-stripes; distally to the apex of the cell an oblique band of white spots, which is sometimes entirely absent above, but in that case is still indicated beneath; hindwing with a chalky white area, which consists of at least 5 patches of which the 4. is the longest (in *helenus, chaon, iswara* and *iswaroides* the 3. is the longest), above no submarginal spots, but beneath a nearly always complete row of white submarginal lunules, of which the 4. and 5. as in *P. chaon* are usually joined to the marginal spots, the white discal area prolonged to the abdominal margin, but the last spot often very small. ♀ much paler than the ♂, the white markings larger and mostly somewhat yellowish above. Malacca to Java and Borneo. Flies in the same localities as *P. helenus*, but does not ascend so high and is not so common. It is a restless and very swift flier, which is fond of visiting flowers, at which, however, it never feeds for more than a short time. The larva resembles that of *helenus* and lives on Citrus; the pupal stage lasts about 14 days
saturnus. (Martin). — **saturnus** *Guér.* (= neptunus *Guér.* in tab.) (22 a). Forewing on both sides with white subapical band, the last spot of the band long and narrow; the white area of the hindwing on the upper surface consists
albolineatus. in ♂ and ♀ of 5 patches. Malay Peninsula, Penang. — **albolineatus** *Forbes.* The spots of the subapical band and the 5. patch of the area of the hindwing on the whole somewhat larger than in *saturnus*; in the ♀ the area of the hindwing also above extended to the abdominal margin; the two last spots sometimes indicated
siporanus. also in the ♂. Sumatra and Borneo. — **siporanus** *Hagen*, from Pora, Mentawei Islands (west of Sumatra); only 1 ♀ known. The white markings larger than in the preceding forms, the yellow-white spot placed before the hindmargin of the forewing above anteriorly continued so far that it joins the broad subapical band; the
tellonus. white area of the hindwing extended to the abdominal margin, the apex of the cell in both wings white. — **tellonus** *Fruhst.*, from the Batu Islands. Probably not different from *siporanus*, but as only ♂♂ are known, the question cannot as yet be settled. The subapical spots of the forewing larger than in the other forms with the exception of *siporanus*, before the hindmargin of the forewing also above a white spot; the white area
uranus. of the hindwing above consists of 6 patches and there are usually also traces of a 7. spot present. — **uranus** *Weym.* (22 b), from Nias. The subapical band is wanting on the upper surface (♂) or is only weakly indicated (♀).
nephelus. Apparently common. — **nephelus** *Bdv.* (22 b) occurs on Java; the statement of earlier authors that it also flies on Celebes is certainly incorrect. The subapical spots sharply developed, but smaller than in *saturnus* and *albolineatus*, more widely separated, before the hindmargin of the forewing above also in the ♀ no distinct yellow spot, the white area of the hindwing above consists in ♂ and ♀ of 5 patches. Beneath the forewing before the apex and the hindwing from the base to the white area are more thickly scaled with yellowish than in *saturnus* and *albolineatus*.

P. nubilus. Similar to *P. nephelus*; small, the subapical spots of the forewing not sharply defined either above or beneath, more or less dusted with black, the 3. and 4. spots placed much nearer to the cell than in *P. nephelus*, the 4. far removed from the distal margin; hindwing above with white discal band consisting of 7 patches, of which the 3. and 4. are the longest, no submarginal spots above, beneath a complete row, all white,
nubilus smaller than in *P. nephelus*, especially the 4., 5. and 6. The ♀ not known. Borneo and Sumatra. — **nubilus** *Stgr.*,

from Brunei, North Borneo, 1 ♂ in coll STAUDINGER. Forewing above with 2 oblong subapical spots, below which a third is indicated, beneath before the hinder angle a patch consisting of 3 white spots; all the submarginal lunules on the underside of the hindwing distinct. — **musianus** *Rothsch.* (39 d), from South-East Sumatra. Forewing above with 3 subapical spots, below which a fourth is indicated, beneath with an anal spot, before which a second, very small one is placed; the 4. and 5. submarginal spots of the hindwing beneath extremely small. 1 ♂ in the Tring Museum, from the hills west of Palembang. *musianus.*

P. chaon. Very nearly allied to *P. helenus.* Palpi laterally entirely white. Forewing in the ♂ without pilose stripes on the upper surface, beneath with a white spot or a white patch consisting of 2 or 3 spots before the hinder angle; on the upper surface of the hindwing a chalky white area consisting of 4 patches, commonly a small 5. spot behind it, beneath nearly always with 3 spots between the white area and the abdominal margin, the submarginal spots not developed above, beneath on the contrary almost always present, grey-yellow. The ♀ paler than the ♂, especially on the disc of the forewing; the white patch before the hinder angle of the forewing beneath, the submarginal spots of the hindwing and the spots placed between the white area and the abdominal margin larger than in the ♂, the two submarginal spots placed before and behind the tail usually joined to the marginal spots placed at its base, which also often occurs in the ♂. The earlier stages unknown, probably very similar to those of *P. helenus.* The butterfly is a forest species which flies together with *P. helenus,* but does not appear to ascend so high in the mountains; it is commonest in the wooded hills. Its area of distribution extends from Central China and Formosa southwards to Cochinchina, Siam and Tenasserim and westwards to Nepal. On Malacca and the Sunda Islands the butterfly is represented by the very nearly allied and perhaps not specifically different *P. nephelus.* — **chaon** *Westw.* (= duketius *Fruhst.*, dispensator *Fruhst.*) (22 b, c). *chaon.* The 4. patch of the hindwing above shorter than the 3.; the yellowish stripes on the upper surface of the forewing and the cell-stripes on the under surface of both wings very distinct. The size of the white patches on the hindwing and of the submarginal spots, as well as the length of the wings, is very variable; in some of the specimens before me from Assam and Sikkim the submarginal spots are only indicated. A ♀ from Sikkim, in which the cell of the „forewing is covered with white scales almost to the middle", was described by FRUHSTORFER as ♀-ab. **leucacantha.** In a ♂ in the Tring Museum, from Cherra Punji, Assam, the yellow submarginal spots of *leucacantha.* the hindwing are extraordinarily enlarged, the 1. and the 7. spot are almost as large as the 2. white discal patch: ab. **paryphanta** *ab. nov.* (32 b). The characters given by FRUHSTORFER for specimens from Tonkin and Siam are *paryphanta.* not constant. Nepal, Sikkim, Assam, Burma, Tonkin, Siam, Cochinchina; common in river-beds in wooded hills. — **ducenarius** *Fruhst.* ♂: the white area of the hindwing larger than in the preceding form, the 4. patch *ducenarius.* anteriorly produced into a long point which projects beyond the 3. patch. Tenasserim. — **chaonulus** *Fruhst.* *chaonulus.* (= durius *Fruhst.*). Smaller on an average than the preceding forms, but many specimens larger than the smallest examples of the subspecies *chaon.* The stripes on both sides of the forewing and in the cell of both wings beneath less distinct. Hainan, China, Formosa.

P. helenus. Body black, occiput, pronotum, palpi and breast with white dots. Wings brown-black, the forewing above in the ♂ thickly hairy on the disc, without markings except 4 faintly visible stripes in the cell, beneath with two whitish stripes on the disc between each pair of veins. Hindwing with white discal area, which in the ♀ is usually more prolonged anally than in the ♂, and in both sexes consists of 3 or 4 spots, of which the 3. is the largest. The submarginal lunules of the hindwing red, above usually only the last distinct, beneath a small red discal spot before the anal spot. The ♀ paler than the ♂, the disc of the forewing above slightly lighter, the submarginal spots of the hindwing above more distinct. The larva on Zanthoxylum and Citrus, when full-grown bluish green, the thorax much swollen, above the legs a lateral stripe, brown anteriorly and white posteriorly, from which projects upwards on the 4. segment a brown belt, on the 7. an oblique white one and on the 9. a second white one, last segment white, on the thorax in addition a transverse band, which terminates at each side in a black spot. Pupa very strongly curved. The butterfly is a forest species, which occurs especially in high jungle. The flight is very swift and irregular, the butterfly is consequently not easy to catch in spite of its abundance. It is most plentiful at low elevations, but ascends to about 6000 ft.; it often settles at puddles on shady forest-paths and also visits flowers. In the northern districts the specimens of the spring brood are smaller than the summer ones and have usually larger red submarginal spots on both sides of the hindwing. Area of distribution: from South Japan (Kiushiu), West China and North-West India southwards and eastwards to Timor. Not known from Celebes. — **nicconicolens** *Btlr.* (= ? semnus *Fruhst.*), from *nicconicolens.* Kiushiu and the Loo Choo Islands Oshima and Okinawa. The summer specimens, f. **nicconicolens** (vol. I, pl. 5 c), large, the white area of the hindwing narrow, the yellow-red spots of the hindwing at least in the ♂ above usually only very weakly developed. The spring form, f. **orosius** *Fruhst.* (= ? semnus *Fruhst.*), is smaller, the white *orosius.* area of the hindwing is mostly broader, and the yellow-red spots of the hindwing beneath are larger. The differences given by FRUHSTORFER between specimens from Kiushiu and Oshima are not confirmed by our examples. It therefore appears to me best to regard the *helenus* from Kiushiu and the Loo Choo Islands as belonging to a

single subspecies until differences in some measure constant are established. — **fortunius** *Fruhst.*, from Formosa. According to FRUHSTORFER the ♂ differs „from *helenus* from Hong-Kong and especially *nicconicolens Btlr.* from Kiushiu by the narrow red submarginal crescents and still more by the strongly reduced white markings of the hindwing beneath, which recalls *palawanicus Stgr.*" A pair in the Tring Museum, belonging to the spring form (taken in March and April), and 4 other ♂♂ without date of capture have the red submarginal spots well developed, and so closely approach specimens from Hong-Kong that scarcely any differences can be seen; the grey-white discal stripes of the forewing beneath seem to be somewhat longer in the Formosa specimens. — **helenus** *L.* (= aulus *Fruhst.*) (21 b, from Hong-Kong). As in the preceding forms the red submarginal spots of the hindwing beneath are all developed; the 2. and 3. patches of the white area of the hindwing are longer and the 1. patch is in proportion smaller than in *nicconicolens*; neither in the ♂ nor the ♀ is a 4. distinct discal patch present. The Hainan specimens, which FRUHSTORFER calls *aulus*, are said to be distinguished from *helenus* by their smallness; I can find no difference at all. The smallest spring specimens are connected with the largest summer ones by all the intermediate grades (length of the forewing in our series 43—70 mm). In ab. **rufatus** *Rothsch.* (32 b) the white area of the hindwing is very strongly reduced, the first patch of the area is beneath very small or entirely absent; on the other hand the marginal cell placed between the two median veins is beneath filled up with red from the discal to the submarginal spots; 2 ♂♂ from Sikkim, in the Tring Museum. In a third ♂, from the Naga Hills, this red area is developed also above. In western China and North-West India *helenus* is rare, in South China, Tonkin, North India and Burma on the contrary rather common; this typical *helenus* occurs southwards to Siam and the Malay Peninsula. — **daksha** *Moore* is the largest *helenus*-form, and has a wing-expanse of 48 to 75 mm; most specimens are large. The white area of the hindwing is large, it touches the cell or extends somewhat into it, the first patch of the area is especially broad; the red submarginal spots are all present beneath; the white-grey discal stripes of the forewing beneath are short. In wooded districts of South India, from Poona (near Bombay) southwards. — **mooreanus** *Rothsch.* (21 c). On an average much smaller than *daksha*; the white-grey discal stripes of the forewing beneath short; the hindwing beneath with a complete row of red submarginal and blue discal lunules. Ceylon. — **hystaspes** *Fldr.* (= varasi *Reak.*) occurs on the Philippines, apparently on all the islands of the group. The white area of the hindwing consists of 4 large patches, which in ♂ and ♀ are almost as large beneath as above. The red submarginal patches are either all present or some of them absent, sometimes only the two posterior ones are developed. — **palawanicus** *Stgr.*, from Domaran, Palawan and Balabac, probably also occurs on Banguey. The white area of the hindwing consists of 3 patches, to which is added in the ♀ beneath a small dirty white 4. spot, the patches much larger above than beneath, the 1. in the ♀ almost square, the 3. placed close to the cell or entering it, not longer (mostly even shorter) than its distance from the margin. On the under surface of the hindwing in the ♂ at least the submarginal lunule behind the tail is wanting. — **enganius** *Doh.* (= helenus *auct.* pt., palawanicus *Rothsch.* pt.). The white area of the hindwing almost as in the true *helenus*, the 1. patch smaller than in *palawanicus*, the 2. and 3. on the other hand larger, the 3. longer than its distance from the margin. Beneath are added in the ♀ 1 or 2 smaller spots, also the ♂ has commonly a small white dot behind the white area; the two submarginal lunules placed before and behind the 3. radial are absent or small. On Borneo, Sumatra and the neighbouring islands, as well as on Java and Lombok. — **tambora** *Rothsch.* Similar to the preceding form, but both the anal red spot on the underside of the hindwing and the red discal spot placed near to it much enlarged. Sumbawa; only a number of ♂♂ known to me. — **mangarinus** *Rothsch.* The white-grey discal stripes on the forewing beneath longer than in the two preceding forms, the red anal spot on the under surface of the hindwing and the discal spot placed near to it larger than in *enganius*, but smaller than in *tambora*; the 4. and 5. marginal spots of the hindwing long and very thin. Flores, a number of ♂♂ in the Tring Museum. — **jindanus** *Rothsch.*, from Sumba. Large, the forewing in ♂ and ♀ strongly curved, the hindwing longer and posteriorly narrower than in the other subspecies of *P. helenus*, the white area of the hindwing large, the 3. patch above almost twice as long as its distance from the end of the 1. radial; the anal and discal red spots on the underside of the hindwing as large as in *mangarinus*, also the 1. submarginal spot large. The disc of the forewing on the upper surface decidedly lighter in the ♀. — **biseriatus** *Rothsch.*, from Timor, only 3 ♀♀ known, which DOHERTY caught at Dili (in Portuguese Timor) and Oinanisa (in Dutch Timor). The disc of the forewing above with a kind of light band, the distal margin less incurved than in *jindanus*, the white area of the hindwing somewhat broader than even in the preceding form and posteriorly prolonged in a point to beyond the 3. radial; the hindwing above with 5 red submarginal spots, the marginal spots larger than in *jindanus*, the posterior ones reddish proximally, the wing broader between the anal angle and the end of the 2. radial than in the preceding form. Beneath the white-grey stripes of the forewing are sharply cut off proximally and their ends (distinctly lighter in 2 out of the 3 specimens) form an interrupted white line, which is widened costad; on the hindwing the white area is continued by 2 spots; distally to each of these two spots is sometimes placed a red lunule (these two lunules are sometimes also developed in *tambora*), the red submarginal spots all present, the spots placed at the anal angle about as large as in *jindanus*.

fortunius. *helenus.* *rufatus.* *daksha.* *mooreanus.* *hystaspes.* *palawanicus.* *enganius.* *tambora.* *mangarinus.* *jindanus.* *biseriatus.*

P. iswaroides. ♂ confusingly similar to *P. helenus*. Forewing above with yellowish discal stripes, beneath the posterior discal stripes are broader and purer white than in *helenus*; hindwing beneath with larger marginal

spots than in *helenus* and with only 2 red submarginal lunules, as the 5 anterior lunules are wanting. Genitalia: the two infra-anal processes of the last (= 10.) segment pointed, but obtuse; the harpe, which in *helenus* is twisted somewhat like a corkscrew, is placed in *iswaroides* before the middle of the anal clasper, is much narrower than in *helenus* and its free part is simply curved inwards away from the clasper, without being twisted half round. The ♀ not known. Sumatra and Malacca, probably more widely distributed, but mistaken for *helenus*. — **curtisi** *subsp. nov.*, from Selangore, Malay Peninsula; only 1 ♂ known to me. The discal stripes placed between the 3. radial and the 2. median on the under surface of the forewing only as long as the black marginal area is broad; the white area of the hindwing narrower than in the next form. — **iswaroides** *Fruhst.* (21 c) flies all the year round in the mountains of Sumatra, where Dr. MARTIN's collectors captured a rather large number. All the discal stripes of the forewing beneath at least twice as long as the black distal margin is broad; the 2. white patch of the hindwing about twice as long as its distance from the distal margin. *curtisi.* *iswaroides.*

P. iswara. Very similar to *P. helenus*. Palpi entirely white; the white area of the hindwing consists of 4 patches, of which the 3. is the largest; the area in the ♂ smaller beneath than above, with the exception of the 4. spot, which is larger beneath, between it and the red anal eye-spot in the ♀ two more white spots, of which at least the upper one is also distinct in the ♂, mostly only 2 red submarginal spots present, both large, usually forming a ring-spot with the marginal spots, before the anal submarginal spot no red discal spot as in *P. helenus*, but always 3 blue lunules. The disc of the upper surface of the forewing in the ♂ with pilose hairs. The ♀ paler than the ♂, the red submarginal spots larger on both surfaces. The genitalia similar to those of *P. helenus*, the harpe of the ♂ more spoon-shaped and the infra-anal processes shorter. Like *P. helenus* occurring in wooded districts, principally in the hills. The early stages not known. Distributed from South Tenasserim to Sumatra and Borneo; only locally plentiful. — **iswara** *White* (21 c). The white area of the hindwing posteriorly broad; the yellow-red spots of the underside of the hindwing large, the anterior ring-spot also in the ♂ always entire, the black pupils of both the eye-spots in the ♀ small. Lower Tenasserim, Malay Peninsula, Penang, Sumatra, Banka. The specimens from the last two islands approximate to the next form. — **araspes** *Fldr.* On an average smaller than *iswara*, but the largest specimens much larger than the smallest *iswara*. The white area of the hindwing mostly not so broad as in *iswara*, posteriorly more pointed; the red spots of the hindwing beneath and the 4. white discal patch smaller. One of the two ♀♀ in the Tring Museum from Lawas, North Borneo, bears on the underside of the hindwing anteriorly 3 thin red submarginal lunules, before the 1. median a fine red longitudinal curved mark and before the tail traces of another submarginal spot, so that the complete row of submarginal lunules is at least indicated. Borneo and Natuna Islands; our two specimens from Bungaran, Natuna, approximate a little to *iswara*. *iswara.* *araspes.*

P. sataspes. Similar to *P. iswara*, but the 2. segment of the palpus black, the white area of the hindwing smaller, in two of the three *sataspes*-forms very much reduced above and entirely or almost entirely absent beneath; the submarginal spots of the hindwing yellow, the 5. rarely indicated, commonly also the 3. and 4. suppressed. Celebes, Bangkai and Sulla Islands, not rare in the hills. — **sataspes** *Fldr.* (22 a) is distributed over the whole of Celebes. The white area of the hindwing above and beneath consists of 3 large patches, to which in the ♀ is added a 4. spot, which is especially distinct beneath. — **artaphernes** *Honr.* The very much reduced white area of the hindwing only extends above to the 2. radial and is almost suppressed beneath. Bangkai; not known to me in nature. — **ahasverus** *Stgr.* (22 a), which is perhaps identical with the preceding, flies on the Sulla Islands, where the ♂ is not rare; the area of the hindwing even smaller than in *artaphernes*, never reaching the 2. radial, beneath only the 2. spot indicated by a very thin line. In the ♀ the area of the hindwing above is still narrower than in the ♂ and beneath there are 2 thin lunules in its place. Only known to me from Sulla-Mangoli. *sataspes.* *artaphernes.* *ahasverus.*

P. diophantus *Smith* (= diaphantus, *Hagen*) (22 c). Distinguished from all other Papilios by 2 narrow red longitudinal stripes which are placed on the under surface of the hindwing, one at the base of the costal margin and the other behind the costal vein. The whitish discal stripes of the forewing beneath condensed posteriorly into a narrow band. Hindwing with a cream-coloured area, which is strongly dentate distally at the veins and beneath is prolonged as a band to the abdominal margin; neither above nor beneath with submarginal spots, the marginal lunules long, the extreme tip of the tail cream-coloured. The ♀ paler than the ♂, the discal band of the forewing, which consists of short stripes, is also present above and disappears costally; the band of the hindwing distinct also above to the abdominal margin, but the posterior 3 spots brownish. This peculiar species is so far only known from Sumatra, where it flies in the mountains from 1000 m upwards all the year round; the ♀ is seldom taken. *diophantus.*

P. fuscus. Body similar to that of *P. nephelus*, palpi laterally entirely white. Forewing in the ♂ without scent-stripes, hindwing with white discal band, which is always broader above than beneath and either extends

to the abdominal margin or is shortened, being beneath sometimes entirely absent; distally to this band above almost always indistinct spots of scattered scales, beneath always at least some blue discal spots present; the submarginal spots yellowish red; the stripes in the cell of both wings somewhat indistinct, the cell of the hindwing beneath mostly strewed with light scales similarly to the base of the subcostal area. The forewing commonly with a white, not sharply defined discal band, which is sometimes widened anteriorly into a broad area, which occasionally is alone developed. The ♀ similar to the ♂, but paler, the markings mostly larger. The eggs laid singly upon Citrus leaves near their tips on the upper or under surface, light green or pale yellow. Larva when young dirty green, anteriorly and posteriorly whitish, with black V-spot in the middle of the back; at each end of the back a row of small white spines; head glossy black. The full-grown larva very variable in colour, usually brown-red mixed with yellow and olive-green, the underside pale greenish or whitish, posteriorly at the thorax begins an oblique lateral band, smaller oblique lateral spots also on some other segments, the pronotum and the 11. segment with a pair of tubercles. The pupa glossy green, beneath in the middle strongly convex, dorsally only very feebly incurved, with short thoracic horn, the wing-cases uniformly projecting, the contour of the pupa viewed from above forming almost a parallelogram, the head truncate and produced into a point at each side. The butterflies in open forests with undergrowth. Distributed from the Andamans to the Solomon

andamanicus. Islands, but wanting on Sumatra, Java and the small Sunda Islands, and also on the Philippines, — **andamanicus** *Rothsch.* (22 b). Until recently united with *prexaspes*. The forewing on the upper surface and beneath on the disc, as well as the basal half of the hindwing beneath, more thickly dusted with yellowish; the 4. patch of the yellowish white area of the hindwing shorter than in the two next forms; above no orange-coloured anal spot; under surface of the hindwing with a blue spot at the distal side of each discal patch. In the ♀ the fore-

dayacus. wing has beneath a white band, which is indistinct behind the middle. Andamans. — **dayacus** *Rothsch.* ♂: the hindwing above with distinct 4. discal spot, beneath the 3. and 4. patches do not reach the cell, the 3 lowest patches of the white band large. ♀: forewing above with narrow diffuse white band, which reaches the hindmargin and is very much widened distally to the apex of the cell; beneath the band purer white and the cell with a white spot in the apex; the yellow-white band of the hindwing is broad, prolonged to the abdominal margin, and enters the cell; the marginal and submarginal spots of the under surface large. North and South Borneo. —

prexaspes. **prexaspes** *Fldr.* occurs in the Malay Peninsula. On the under surface of the hindwing the 6 anterior blue discal spots, if present at all, are very small, the 5. and 6. white discal spots are smaller than the 1., and the 1. does

pertinax. not extend beyond the lower extremity of the 3. The ♀ not known to me. — **pertinax** *Wall.* (= metagenes *Fruhst.*). Costal margin of the forewing strongly curved; on the forewing a yellowish white discal band which at least beneath is distinct before the hindmargin, gradually disappears anteriorly and varies very much both in length and breadth; the white area of the hindwing above does not reach the cell, it consists of 3 patches, to which often a 4., diffuse, patch is added, sometimes the area is connected with the abdominal margin by sparse grey scaling. In small specimens the costal margin of the forewing is generally less strongly curved than in large

minor. ones. The name ab. **minor** *Oberth.* refers to small specimens. In all the localities *pertinax* varies considerably in the markings, especially on the under surface. Sangir and Talaut Islands, the whole of Celebes, Salayer,

porrothenus. Toekan Bessi and Sulla Islands. — **porrothenus** *subsp. nov.* Shape of the wings similar to that of *pertinax*; forewing 38 to 52 mm long; the yellowish white area of the hindwing above posteriorly produced into a thin band, which usually reaches the abdominal margin, the 3. patch much longer than its distance from the distal margin (usually twice or even three times as long); the submarginal spots of the hindwing beneath small and pale, also in the ♀, often almost all wanting, the 7. small or not developed at all. Kalao and Dyampea (= Djampea),

lapathus. south of Celebes; a number of ♂♂ and 1 ♀ collected by A. Everett in December 1895. — **lapathus** *Fruhst.*, from the North Moluccas: Morty, Halmaheira, Ternate and Batjan. Forewing beneath, sometimes also above, before the hindmargin with a narrow discal band, which disappears anteriorly or widens distally to the apex of the cell into a broad but indistinctly defined light patch, distally at the apex of the cell no distinct white spots are present; both wings, but especially the hindwing, shorter than in the race from the South Moluccas; the yellowish white area of the hindwing varies in length and breadth, and the yellowish grey or blue scaling placed distally to it is not condensed into such distinct spots as is usually the case in the subspecies from the South Moluccas.

ombiranus. Sometimes the tail is reduced to a short stump. — **ombiranus** *Rothsch.* (23 a) flies on the various islands of the Obi Group. Forewing with large, triangular, white area distally to the apex of the cell, this area, which is very seldom absent, usually produced posteriorly into a narrow, indistinct band, which mostly reaches the hindmargin; the white area of the hindwing large, reaching to the hindmargin or at least the 2. median, the anterior veins which intersect it not black, the yellowish grey or bluish dusting distally to the band only weakly developed.

fuscus. — **fuscus** *Goeze* (= madanus *Fruhst.*) (22 c). Forewing without discal band, or, if one is present, with white patches distally to the apex of the cell, the costal margin less strongly curved than in *pertinax*; the band of the hindwing consists of at least 4 patches, it is usually produced into a point posteriorly and very frequently enters

cinereomaculatus. the cell. Three principal forms, which are connected by transitions: f. **cinereomaculatus** *Goeze*: forewing with white spots distally to the apex of the cell, sometimes with a band extending to the hindmargin; f. **fuscus** *Goeze* (= severus *Cram.*): forewing without white spots distally to the apex of the cell, the band of the hind-

castaneus. wing posteriorly running to a point, often entering the cell; f. **castaneus** *Goeze*: forewing without white spots; the band of the hindwing shortened, narrow, consisting of 4 spots. We formerly referred the name

castaneus erroneously to the Celebes form. Southern Moluccas: Buru, Amboina and the neighbouring islands, Ceram, Ceram Laut and Goram Laut. The white patches of the hindwing beneath are commonly so thickly dusted with black-brown that they scarcely stand out from the dark ground, which also very commonly occurs in *ombiranus* and occasionally in *lapathus*. — **thomsoni** *Btlr.* (= langeni *Druce*). Both wings shorter and broader than in the preceding forms, the hindwing more rounded. Forewing above and beneath usually with discal spots distally to the apex of the cell, but never with a white spot or light band before the hindmargin. The white area of the hindwing above always reaches to the 2. median or the abdominal margin, and distally to it there are only traces of blue or grey dusting; on the under surface the white discal spots are entirely absent or very strongly dusted with black, the submarginal spots, which also are frequently absent, are placed somewhat further from the distal margin than in the Moluccan races. Very common on the Key Islands. A remarkably aberrant specimen (♀) has been described as ab. **mordingtoni** *Rothsch.* (30 c): hindwing above with 4 white spots, of which the one placed in the cell is large and diffuse; before the anal angle there are 2 large red spots, which beneath are even larger than above; from Key Toeal. — **rotalita** *Swinh.* (= septimius *Stgr.*). Although SWINHOE gave Key as habitat, there is no longer the slightest doubt that this form only occurs on the Aru Islands. Forewing with 2 to 4 small subapical spots, which above are sometimes only indicated, the 1. the largest, the 2. in the subcostal fork, the distal margin beyond these spots paler than the rest of the wing; the yellowish white band of the hindwing does not enter the cell, the 1. spot is always small, and the band is suddenly much narrowed behind the 4. spot; the red anal spot is always present. Beneath the first white discal spot of the hindwing is very thin, the 2. and 4. are small, the 3. is at most about half as long again as it is broad, but usually almost circular, all these spots remote from the cell. — **offakus** *Fruhst.*, from Waigeu, is not known to me in nature. The description agrees so well with specimens from the Northern Moluccas that an error as to the locality might be suspected. ♀: the wings above copiously scaled with grey-green, the forewing beneath in the distal part with a whitish grey band which is not so light costally as in the following races; the blue spots on the underside of the hindwing much more distinct than in *lapathus* and *beccarii*. — **beccarii** *Oberth.* (27 c). ♂: forewing above before the distal margin with yellowish stripes which become shorter posteriorly and the proximal ends of which are often condensed into a thin macular band; between the subcostals beneath usually a few small white spots, which are sometimes indicated also above, the yellowish white band of the hindwing reaches the abdominal margin and only occasionally enters the cell; beneath there are always at least 4 white discal spots present, of which the 3. and 4. are rarely shorter than their distance from the cell. In the ♀ the band of the forewing beneath is usually somewhat more distinct than in the ♂, but there are never sharply defined white subapical spots as in *rotalita*. Dutch and German New Guinea; very rare in the German district. — **indicatus** *Btlr.* (= yorkeanus *Fruhst.*). ♂: forewing above and beneath with a narrow band, which is broadest anteriorly and often does not reach the hindmargin, the anterior spots of the band distally incised; the band of the hindwing is always separated from the cell and the white discal spots of the hindwing beneath are as a rule all narrow, none of the red submarginal spots are present above except sometimes the anal spot. In the ♀, which is much paler than the ♂, the band of the forewing is more diffuse than in the ♂, and the red anal spot on the upper surface is small or absent. British New Guinea, D'Entrecasteaux Islands, Woodlark, Louisiades, islands in the Torres Straits, Cape York. Common near the coast; MATHEW reports a migratory swarm of butterflies which he observed on the coast of New Guinea and which consisted in great part of specimens of this Papilio. — **capaneus** *Westw.*, from Queensland. Very similar to the preceding subspecies; the anterior spots of the forewing larger, and the hindwing bears above besides the always distinct red anal spot at least in the ♀ several red submarginal spots, often a complete row. The white discal spots of the hindwing beneath and the submarginal spots are mostly larger than in specimens from New Guinea. — **xenophilus** *Mathew* (= epibomius *Fruhst.*) (23 a). On an average much larger than *capaneus*; the band of the hindwing beneath broader beyond the 5. spot. The band of the forewing, which in many specimens is broadly interrupted and beneath is sometimes entirely absent, reaches to the 3. subcostal and is usually broadest anteriorly. On the southern Solomon Islands: Ugi, Guadalcanar, Isabel, New Georgia, Guizo, Rendova. — **hasterti** *Ribbe.* In ♂ and ♀ beneath and in the ♀ also above the band of the forewing is only developed posteriorly; in the ♂ moreover the first spot of the band is only indicated above. Choiseul and Bougainville. — The two ♀♀ taken by WEBSTER, which ROTHSCHILD recorded in 1895 as from Alu, probably came from New Georgia; WEBSTER'S localities were not always reliable. If a form of this species occurs on Alu, it is undoubtedly *hasterti*. — **cilix** *Godm. & Salv.* (23 a). ♂: forewing above without band, in fresh specimens rather thickly dusted with yellowish, beneath with small white spots from the hindmargin costad, the row never prolonged to the costa, frequently suppressed except for a small spot placed before the 2. submedian, occasionally even this spot not developed. The white band of the hindwing above and especially beneath broader than in all the other subspecies of *P. fuscus*, always extending to the abdominal margin. ♀: paler than the ♂, the forewing at least beneath with a whitish discal band which is suppressed anteriorly; specimens with almost white abdomen are ♀-ab. **alboventris** *Ribbe.* New Hanover and New Mecklenburg (= New Ireland). — **lamponius** *Fruhst.* Mostly smaller than the preceding (length of the forewing in *cilix* ♂ 57—67 mm., ♀ 67—70 mm.; in *lamponius* ♂ 50—61 mm., ♀ 62—64 mm.). The other differences given

thomsoni. *mordingtoni.* *rotalita.* *offakus.* *beccarii.* *indicatus.* *capaneus.* *xenophilus.* *hasterti.* *cilix.* *alboventris.* *lamponius.*

by FRUHSTORFER are still less tenable, yet it is a fact that at least in many ♂♂ of *lamponius* the white band of the hindwing above encroaches further on the cell than in *cilix*. According to RIBBE ♀♀ with almost white abdomen also occur. New Pomerania (= New Britain).

P. albinus. Similar to *P. fuscus*. The ground-colour in the ♂ almost pure black; the white area of the hindwing above very broad, always entering the cell, the 2. to the 4. spot distally sharply excised and produced at the veins into a pointed tooth, distally to the white area no grey-blue discal spots; beneath the white patches very sharply defined, especially distally. ♀ much paler than the ♂, the white area of the hindwing as in the ♂, but above mostly somewhat narrower, sometimes not reaching the cell; the hindwing beneath with a white discal band consisting of 6 or 7 patches and a complete row of dirty yellow submarginal spots. Dutch and British New Guinea, at low elevations in the hills. — **albinus** *albinus.* *Wall.* (= sekarensis *Honr.*). Forewing without white subapical band. Dutch New Guinea. In ab. **leucophanes** *leucophanes.* *Gr.-Sm.* the hindwing has only 2 white discal patches beneath. — **lesches** *lesches.* *Godm. & Salv.* (25 c). Forewing with white subapical band. British New Guinea.

P. schmeltzi *schmeltzi.* *Herr.-Sch.* (27 c). ♂: forewing black, commonly anteriorly with traces of a thin, curved white discal band, which is always present beneath. Hindwing with bluish grey discal band, which does not reach the abdominal margin and is very strongly dentate distally; beneath this band is represented by a fairly complete row of thin lunules, distally to which large blue lunules are placed, the submarginal spots, which are wanting above, are beneath ochre-yellow and all very well developed, the veins striped with grey at the base of the hindwing, especially the costal (as in *godeffroyi*). ♀ paler than ♂, forewing also above always with discal band. The freshly laid egg straw-yellow, later orange, before hatching grey. The young larva similar to bird-droppings, with branched spines on all the segments; when full-grown very variable, usually green, with brown thoracic band, which beneath runs laterally to the prothorax, on the abdomen 2 shortened oblique bands, on the 3 thoracic segments and the penultimate abdominal segment low tubercles; the scent-fork vivid red. Pupa always fastened to a twig, blue-green, beneath in the middle strongly convex, dorsally moderately incurved, with silver stripes on the wing-cases and the abdomen, the middle of the abdomen dorsally vivid golden green; on Aralia. The butterfly in the open forest where there is underwood; its flight irregular, jerky. — Fiji Islands; the only Papilio occurring there.

P. godeffroyi *godeffroyi.* *Semp.* (27 c). ♂: forewing rather pointed, with oblique band of white spots distally to the cell, the band beneath continued to the submedian by an interrupted or complete row of narrow transverse spots. Hindwing above with bluish grey discal band, which is pointed posteriorly and does not enter the cell; distally to the band indistinctly defined blue spots; fringe-spots of both wings large. Beneath the band of the forewing only indicated by a faint line, distally to this a complete row of blue lunules, the submarginal spots yellowish grey, not sharply defined, the anal spot yellow-red. The ♀ paler, the forewing with a macular band, continued also above to the hindmargin; hindwing above with several red submarginal spots, beneath the discal band very narrow, white, the submarginal spots all distinct, yellow-red. The young larva black, with white V on the back, and black spines. The full-grown larva variable, usually green and marked similarly to the larva of *schmeltzi*, on the 3. to 5. segments 2 short orange-coloured spines at each side, on the 8. to 12. segments an orange-coloured tubercle at each side; on Aralia. Pupa golden green, the back of the abdomen uniformly convex; always fastened on the midrib of a leaf. The larvae of this species and *schmeltzi* feed by day. — Samoa.

P. ilioneus. Palpi laterally entirely white; abdomen beneath at the sides and in the middle with altogether 5 yellowish white, rather thick lines. ♂: forewing above distally to the cell with an oblique band of white spots and before the distal margin a row of white submarginal dots, of which usually the 1. (placed before the 4. subcostal) is distinct; hindwing with white discal area from the costal margin to the 1. median or somewhat beyond it, the 3. patch always the largest, the last small, placed close to the cell, the apex of the cell always white; the fringe-spots white, large. Under surface: forewing as above, but the oblique band broader and all the submarginal spots except the last well developed, before the submedian a short white discal linear transverse spot; the discal band of the hindwing continued to the anal margin, a complete row of submarginal spots, the first and last large, rounded and yellow-red with yellowish white margin, the others yellowish white with red dots. The ♀ paler brown, the markings of the forewing yellowish, larger than in the ♂, before the hindmargin at $^2/_3$ a triangular patch. On New Caledonia and the neighbouring Loyalty Islands, as well as on Norfolk Island. — **ilioneus** *ilioneus.* *Don.* (= amphiaraus *Fldr.*). ♀: the subapical band of the forewing above broad, yellowish; the submarginal spots of the hindwing beneath large, the 2. and 3. at least as large as the black spots which are placed between them and the yellowish white discal area. Norfolk Island. — **amynthor** *amynthor.* *Bdv.* (= abstrusus *Bllr.*) (27 c). The subapical band of the forewing and the posterior patches of the yellowish white area of the hindwing less narrow than in the preceding form, the band of the forewing narrower and the submarginal spots on the under surface of both wings smaller. New Caledonia and the Loyalty Islands; apparently common.

P. canopus. Both wings in ♂ and ♀ with a white or yellowish band, which beneath is at least as broad as above. The band of the forewing in some tailless forms suppressed except for the 1—3 subapical

spots, sometimes also that of the hindwing only indicated by a few small, thin spots; these forms recall brown forms of *P. clytia*, but are easy to distinguish by the thin marginal spots and the much more distal position of the subcostal vein of the hindwing. In *P. fuscus capaneus* and *xenophilus*, which resemble the tailed *canopus*-forms, the continuous band of the hindwing above is beneath much narrower and broken up into spots. On the small Sunda and the Tenimber Islands, in North Australia and on the New Hebrides. — **hypsicles** *Hew.* The band of the forewing running straight from the subcostal fork to the hindmargin, *hypsicles.* somewhat obliquely placed, posteriorly somewhat widened, the spot placed in the subcostal fork not longer than the 1. or 3. spot; the blue discal spots on the hindwing beneath rather large, the submarginal spots reddish, the 5. and 6. patches of the white band about 1/3 as long as their distance from the submarginal spots. The tail spatulate. New Hebrides. — **canopus** *Wcstw.* The spot of the band of the forewing placed *canopus.* in the subcostal fork longer than the 1. and 3. spots, the central spots always smaller than the anterior ones; the abdominal margin of the hindwing shorter than in *hypsicles*, hence the discal band and the subcostal spots nearer together. Tail spatulate. North-West Australia and Cape York. — **tenimberensis** *tenimberensis.* *Rothsch.* (= babberensis *Fruhst.*). Similar to the preceding subspecies, but the band on both wings much broader. The ♂ without distinct submarginal spots on the upperside of the hindwing, these spots in the ♀ sometimes sharply expressed and red-yellow. Tenimber; Babber. — **croton** *Fruhst.*, from Dammer, is *croton.* so variable that there are no reliable differences from *canopinus* on the one hand and *tenimberensis* on the other. In some specimens the band of the forewing is almost obsolete beyond the 4. spot, whilst in others it is as broad as in *tenimberensis*; the band of the hindwing is in some specimens only 1/3 as broad as in others. The submarginal spots of the hindwing, which above are only rarely absent, are small and usually diffuse. Our series of 15 specimens was taken by H. Kühn from the 31. October to the 12. December 1898. — **canopinus** *Rothsch.* (= kallon *Fruhst.*) (24 c), from Roma and Moa (perhaps occurring also on the other *canopinus.* small islands of the group), likewise varies rather strongly; the band of the forewing is placed nearer to the distal margin than in the preceding races; the submarginal spots of the hindwing are also above always large; the tail is either widened at the end, or simply pointed, or reduced to a short tooth which scarcely projects more than the other marginal teeth. — **hypsiclides** *Rothsch.*, from Wetter, is even more variable than *croton.* *hypsiclides.* The band of the forewing, at least on the under surface, is not placed posteriorly so near to the margin as in *canopinus* and *vollenhovii*, it varies in width, especially from the 4. spot, and is sometimes widely interrupted; the central spots of the band of the hindwing are usually much shorter than their distance from the cell, the submarginal spots of the hindwing are also above always sharply developed; the tail is either feebly spatulate, or simply pointed, or is completely absent; in tailless specimens the distal margin of the hindwing is sometimes much less rounded than normally. — **vollenhovii** *Fldr.* (24 c), from Timor, is always tail- *vollenhovii.* less, the band of the forewing is placed close to the distal margin and is always broad; the band of the hindwing is broader than in most specimens of *hypsiclides*, the 5. and 6. patches are always considerably longer than their distance from the submarginal spots, the latter are well developed above and beneath and the 6 anterior ones in our 8 specimens white above. Doherty found this form in Dutch Timor in November and December. — **alorensis** *Rothsch.* (24 c). Tailless. The band of the forewing obsolete except three sub- *alorensis.* apical spots and traces of the posterior ones, the 1. spot only indicated, the 2. (placed in the subcostal fork) larger and distinct, the 3. small; the band of the hindwing very narrow, the submarginal spots further removed from the distal margin than in *vollenhovii*. Alor, only 1 ♂ known, taken by Doherty in October. — **umbrosus** *Rothsch.* (30 c). Tailless; brown, the distal margin of both wings paler brown; forewing without *umbrosus.* band, only with a spot in the subcostal fork; the discal band of the hindwing indicated by very thin, small spots, the submarginal spots small above, rather large beneath. Sumbawa; Doherty caught a pair in September. — **sumbanus** *Rothsch.* (24 c). Forewing with 3 large subapical spots and a small double *sumbanus.* spot at the hindmargin; hindwing without tail, the discal band on both sides very thin or scarcely indicated, the submarginal spots are wanting above and are beneath all white, linear and somewhat diffuse. Sumba; a pair in the Tring Museum. A rather faithful copy of *Euploea lewa* from the same locality, but larger.

P. hipponous. Forewing not far from the distal margin with a narrow band running forwards from the hindmargin, which above is yellowish and sometimes absent, and beneath white and sometimes reduced to a small double spot. Hindwing with a white band, broken up into spots by the black veins, which is of almost equal width above and beneath and always reaches to the abdominal margin. The ♀ very similar to the ♂, but somewhat paler. Nothing is known as to the earlier stages. The ♂♂ drink at puddles and springs. Indo-Malayan. — **pitmani** *Elw.* (= pitmanni *Rothsch.*). Forewing above without distinct band, *pitmani.* at most with a small spot before the hindmargin. Tenasserim and Siam. — **hipponous** *Fldr.* Forewing *hipponous.* above with distinct yellowish band, which gradually disappears costally; the 3. spot of the band of the hindwing about twice as long as the 5. On Luzon. — **bazilanus** *Fruhst.* Very similar to the preceding form, *bazilanus.* but the band of the hindwing of more uniform width, the 3. patch being shorter than in *hipponous.* Palawan, Bohol, Mindanao, Bazilan. — **lunifer** *Rothsch.* (33 b). A very large form, in which the submarginal *lunifer.* spots of the hindwing beneath are large and strongly curved and placed further from the distal margin *lepto-* than in the other forms. Sangir and Talaut Islands. — **leptopsephus** *Fruhst.* Forewing with an anteriorly *psephus.*

shortened white submarginal band; the ochreous submarginal lunules of the hindwing beneath very small. Assam, the locality however is doubtful. Not known to me in nature; is it different from *bazilanus?*

sakontala. **P. sakontala** *Hew.* (32 c). ♂: both wings narrower than in *P. hipponous* and *P. polytes.* Forewing with narrow marginal spots and grey discal stripes, without the band of *P. hipponous*; hindwing with a discal band composed of separated patches more or less strongly dusted with black, in which the 4. and 5. spots are the longest; the reddish submarginal spots of the hindwing beneath are very small, some of them not developed. — A rare North Indian species, of which so far only a few specimens have been found; from Mussourie eastwards to the Naga Hills in Upper Assam.

jordani. **P. jordani** *Fruhst.* Brownish black. Forewing from the 5. subcostal backwards with chalk-white marginal spots, the first two small, the others large, the 4. and 5. nailhead-shaped. Hindwing with discal macular band and large marginal spots, all chalk-white, but the marginal spots, as well as those on the forewing, above dusted with black; the discal spots very large, especially the 3.—5.; submarginal spots wanting. Both wings elongated, the hindwing strongly dentate, but without tail. — 1 ♂ in coll. FRUHSTORFER, probably from Celebes.

walkeri. **P. walkeri** *Jans.* (32 c). Only 1 ♂ known. Forewing with grey discal stripes and white marginal spots. On the upper surface of the hindwing a diffuse, broad grey-blue discal band and a complete row of blue-grey submarginal spots; beneath the submarginal spots are yellowish, the blue discal band is reduced to spots and on the proximal side of the posterior blue spots are placed yellow ones; the tail short, not spatulate. — South India; in the Tring Museum.

Polytes Group.

Sexes different. The ♀♀ mimics of Aristolochia-Papilios, in *P. polytes* polymorphic and one of the ♀-forms similar to the ♂. Closely connected with the preceding group by *P. eanopus, hipponous, sakontala*, etc., and with the following one by *P. ambrax.*

P. polytes. Palpi pure white at the sides. ♂: black, forewing with white marginal spots which are narrower at the distal margin than towards the disc, after the manner of a nail-head; hindwing with white, rarely yellowish discal band outside the cell, which consists of spots of about equal size and is almost the same beneath as above. The ♀ occurs in 3 principal forms: the *cyrus*-form is very similar to the ♂; the *theseus*-form has on the hindwing red discal patches instead of white ones; and the *polytes*-form bears white discal patches on the hindwing. In all the ♀♀ of the 2. and 3. form the forewing is black from the base to the 1. or 2. median and at the distal margin, the posteriorly narrowed central area lighter and traversed by black vein- and fold-stripes, the distal margin distinctly undulate, with thin white fringe-spots. Distributed from North-West India, West China and the Loo-Choo Islands southwards and eastwards to the Moluccas and Timor with the neighbouring islands; not yet known from Tenimber. The larva lives principally on species of Citrus, but also occurs on other trees, as Murraya, Triphasia, Zanthoxylum; when young similar to bird-droppings, the full-grown larva green, the thoracic legs reddish, prolegs pale green, above the legs a white longitudinal stripe, on the thorax a transverse band, which terminates at each side in a black spot, behind the thorax a second belt which is joined to the white lateral stripes, in the middle of the body two oblique bands, all white with brown or green spots. The pupa olive-brown, with brown, green and yellow spots and stripes, the underside of the abdomen milk-white, or the whole pupa green; the horns on the head short, obtuse, rather widely separated, the thoracic horn short, the dorsum at the base of the abdomen rather strongly incurved, the wing-cases moderately protruding (the figure in MOORE, Lep. Indica Tab. 462 is not correct). One of the commonest Indo-Malayan Papilios; everywhere in open woods and in gardens, at low elevations, in the Himalayas up to about 6000 ft. The flight of the ♂ is very swift, restless, oscillating, whilst the ♀ sails more slowly and in this also resembles those Aristolochia-Papilios to which it approximates in the markings. *P. polytes* is fond of visiting flowers, but is never found at wet places on the roads. The different ♀-forms fly at the same time, but are not equally common, also in some districts only one or two forms occur. The geographical forms are in general not sharply distinguished. We differentiate two groups of forms: 1) The ♂ has blue scales on the under surface at the distal side of the posterior white discal spots in the forms which are distributed from the Loo-Choo Islands southwards over India and the large and small Sunda Islands as far as Babber, whilst 2) these blue scales are extremely rarely present in those forms which inhabit the Moluccas, the Sulla Islands, North Celebes and the Philippines. In North Borneo both groups of forms appear to fly. The larvae of the two groups are said to be distinguished by this (is it constant?), that the saddle-spot in the first group is open above and in the

polytes. second closed. — **polytes** *L.* (= borealis *Fldr.*, polycles *Fruhst.*, pasikrates *Fruhst.*). ♂: the band of the hindwing mostly narrow, the spots usually rather widely separated; in the spring specimens the submarginal

borealis. spots of the hindwing beneath are red and rather large: ♂-f. **borealis** *Fldr.* (see vol. I, pl. 5 c), whilst in the

pammon. summer specimens they are mostly white, some of them often wanting: ♂-f. **pammon** *L.* (31 a). Among

depicta. the latter form occur examples which have no submarginal spots at all and have received the unfortunately

mandane. chosen name ♂-f. **depicta** *Fruhst.* The ♀ occurs in three principal forms: ♀-f. **mandane** *Rothsch.* (= ocha

Fruhst.), similar to the ♂; ♀-f. **stichius** *Hbn.*, hindwing with white discal spots, but without white cell-spot; *stichius.*
♀-f. **polytes** *L.* (31 a), hindwing with white spot in the cell also. Loo-Choo Islands, Formosa, China from *polytes.*
Shanghai to North Tonkin, Hainan, very common. — **romulus** *Cr.* (= ceylanicus *Fldr.*, neomelanides *Fruhst.*) *romulus.*
is the oldest name for the very variable form which is distributed from Tonkin to North-West India and Ceylon in the west and to the Natuna and Lingga Islands in the south. The band of the hindwing in the ♂ broader than in the preceding subspecies, but specimens also occur in which the band is quite as narrow; the spring specimens of the mountains have on the under surface of the hindwing strongly developed red submarginal spots, some of which are sometimes distinct also above. Two ♂♂ from South India in the Tring Museum are very aberrant and somewhat suggestive of *P. sakontala* by the diffuse band of the hindwing above; in both specimens the marginal spots of the forewing are enlarged; in the example from Coimbatore (the nametype) the two posterior discal spots of the hindwing above are small and white, the others are absent or replaced by bluish nebulous spots, which are joined to a second row of bluish spots; beneath 5 white discal spots are present, which form the proximal boundary of long red, bluish and yellowish grey stripes, whose discal ends correspond to the submarginal spots of normal specimens; the second example, from the Nilghirris, has above and beneath oblong bluish grey discal patches; on the left wing the row is complete, whilst the upper spots are wanting on the upper surface of the right hindwing and small on the under surface; on the other hand the right hindwing has beneath a row of submarginal spots which are wanting on the left wing: ♂-ab. **astreans** *ab. nov.* (32 a). The ♀ occurs in the western parts of the area of distribution *astreans.*
in 3 principal forms, in the eastern only in 2. The form similar to the ♂ is ♀-f. **cyrus** *F.* (= cyroides *Fruhst.*) *cyrus.*
(31 a). The band of the hindwing broader than in the corresponding form of the preceding subspecies, in spring specimens the submarginal spots of the hindwing are large and red beneath and often above also. The second ♀-form, with white discal area, varies even more strongly than ♀-f. *polytes*, and only the examples with large cell-spot are distinguishable from Chinese specimens. The 3. form, ♀-f. **romulus** *Cr.* (= mutius *romulus.*
F., astyanax *F.*, rubida *Fruhst.*) (32 a), mimics *P. hector* and occurs also only in the district of this species from Ceylon to North India; in Sikkim, where *hector* does not occur, *romulus* is scarce and further east it has not yet been observed at all: forewing with a short subapical and a longer discal light oblique band, hindwing without white patches, on the contrary with much red. — **nikobarus** *Fldr.* is a large form with *nikobarus.*
broad band on the hindwing. The ♀-form similar to the ♂ appears to be commoner than in other districts. The second ♀-form, with white discal area, is apparently rather rare and not distinguishable from certain
mainland specimens with white cell-spot. Nicobars and Andamans. — **theseus** *Cr.*, from Sumatra (except *theseus.*
the south-east) and Borneo. Smaller on the average than the preceding forms. ♂: tail shorter, less spatulate, the band of the hindwing usually narrower at the abdominal angle than in the ♂ of *romulus*. The ♀-form in male garb., ♀-f. **nonia** *form. nov.*, is distinguished in the same way as the ♂; the ♀ without white *nonia.*
spots on the hindwing, but with red spots, is ♀-f. **theseus** *Cr.* (30 c); in exceptional cases these red discal *theseus.*
spots are developed into long stripes: ♀-f. **melanides** *Deh.*; finally in ♀-f. **numa** *Weber* the hindwing has a *melanides.*
few small white discal spots. — **javanus** *Fldr.* (= antiphus *Deh.* nec *Edv.*, insularis *Piepers*) (31 a, b), from *numa.*
javanus.
South-East Sumatra, Billiton, Java, Banka, Bali. In the ♂ the tail usually reduced to a short stump. An evidently atavistic specimen from Java (in the Tring Museum) has the grey scaling on the upperside of the forewing condensed into a narrow discal macular band, which is obsolescent costally and on the under surface is represented by a very distinct transverse patch placed before the hindmargin: ♂-ab. **seronis** *ab. nov.* *seronis.*
(32 a). In ♂-ab. **gronovii** *Sulz.* the band of the hindwing above is yellow (discoloured?). In the form of *gronovii.*
the ♀ similar to the ♂ the tail is narrower and shorter than in the corresponding ♀ of the preceding race: ♀-f. **pygela** *form. nov.* The *polytes*-form of the ♀ differs from the white-spotted ♀♀ from Sumatra and *pygela.*
Borneo by the much larger white discal spots, in which this form agrees to a great extent with certain specimens of the ♀-f. *polytes* from Malacca, the under surface of the forewing is very pale and the dark basal area is usually extended to the base of the 1. median: specimens from Bali form a transition to the next subspecies. — **vigellius** *Fruhst.*, from Bawean. I have before me only ♂♂, and ♀♀ resembling the ♂, which *vigellius.*
agree with specimens from Java. In the second ♀-form, which I do not know, „the white discal spot hardly ever extends beyond the cell and the forewings have darker stripes than in *javanus*-♀♀". — **messius** *messius.*
Fruhst., from Lombok, common. The ♂ with short obtuse tail, the band of the hindwing narrower than in *javanus* ♀-f. *pygela*. In the white-spotted ♀ the white area of the hindwing is reduced to a few spots placed outside the cell, rarely there is a diffuse spot in the cell; the light area of the forewing is less extended than in *javanus* and *theseus* and above and beneath darker, the tail is usually only very little widened and never so strongly spatulate as in the corresponding ♀-forms of the preceding races: ♀-f. **nuceria** *form.* *nuceria.*
nov. In a third ♀-form the white spots on the hindwing are entirely absent, as in ♀-f. *theseus* from Sumatra and Borneo, but the forewing is not so light as in that form and the tail less spatulate: ♀-f. **tisias** *form.* *tisias.*
nov., mimics *P. aristolochiae lombockensis.* — **sotira** *subspec. nov.* flies on Sumbawa. The band of the ♂ is *sotira.*
on an average even narrower than in the preceding subspecies, the 3. spot of the under surface is usually very narrow. The only ♀-form known to me has a row of 3 or 4 discal spots on the hindwing, cut off straight towards the base; the forewing is above darker than in all the other forms, the light discal area is even more restricted than in *messius*, beneath the black basal area extends beyond the base of the 1. median

timorensis. and the black stripes between the veins are very broad; the tail is spatulate. — **timorensis** *Fldr.* (= polyphontes *Deh.* nec *Bdv.*), distributed from Sumba, Savu and Flores eastwards to Babber. The band of the ♂ broader than in the specimens from Lombok, especially beneath; many ♂♂ have on the under surface of the forewing a white spot before the hindmargin not far from the anal angle; this is the case in all the 5 specimens which we have from the island of Savu. One of these Savu ♂♂ has in addition on both sides of the forewing 4 small grey discal spots, which are placed between the 4. subcostal and 3. radial: ♂-ab. *solia.* **solia** *ab. nov.* The ♀ occurs in 2 principal forms: ♀-f. **virilis** *Röb.* is similar to the ♂; almost all specimens *virilis.* have a white spot on the underside of the forewing before the hindmargin, also the band of the hindwing is still broader than in the ♂. ♀-f. **timorensis** *Fldr.* is usually much lighter on the forewing, the interneural stripes are mostly narrow and the one placed between the two median veins does not generally reach the dark basal area; the white macular area of the hindwing is very variable, but always enters the cell. — *tucanus.* **tucanus** *subsp. nov.* Similar to *alcindor.* ♂♀: forewing posteriorly broader, the costal margin less strongly curved and the distal margin less incurved; the hindwing posteriorly less produced, hence the sinus placed behind the tail almost at the same height as the one placed before the tail; the tail in the ♂ distinctly pointed. In the ♀ the disc of the forewing above and beneath is purer white than in the *alcindor*-♀ and the posterior black stripes are thinner; the black basal area almost reaches the 1. median. The white area of the hindwing consists of a small cell-spot and 5 discal ones, which are all sharply developed; the first of these spots is rhomboidal. Binongka and Kalidupa, Toekan Bessi Islands, taken by H. KÜHN in December *alcindor.* 1901 and January 1902. — **alcindor** *Oberth.* (= thesalphenor *Stgr.*, passienus *Fruhst.*, persienus *Fruhst.*) (31 b). ♂♀: forewing narrower than in all the preceding forms, the costal margin strongly curved (as in many butterflies on Celebes) and the distal margin distinctly incurved before the middle; the hindwing posteriorly prolonged, so that the costal margin of the tail is much longer than the hindmargin. ♂: marginal spot of the forewing large, the posterior 4 or 5 broader than the interspaces. The band of the hindwing comparatively narrow, some specimens with a red spot at the distal side of the penultimate spot; in one of our examples from East Celebes there is a small white spot in the cell. The ♀ occurs in only one form: the dirty white discal area of the forewing reaches basad to the base of the 2. median, the black stripes and the black distal margin are broad. The white cell-spot of the hindwing always reaches the base of the 2. median; there are 3 to 5 spots round the cell, the upper ones are pointed, and the distal margins of all more or less diffuse. A copy of *P. polyphontes*: common on Saleyer and in South, Central and East Celebes, also on Buton; on the northern peninsula of Celebes flies quite another subspecies, which belonges to the following series of forms.

In the remaining forms of *P. polytes* the oblique bands of the abdomen of the larvae, so far as is known, are not interrupted dorsally; the ♂♂ very seldom have blue scales distally to the discal band on the under surface of the hindwing; in the ♀ the 2., and mostly also the 3. submarginal spot of the hindwing beneath is not lunular, but slightly S-shaped, moreover the longitudinal veins traversing the white discal area of the hindwing are very narrowly or not at all scaled with black.

valeria. — **valeria** *subspec. nov.* Only 3 ♀♀ in male garb known to me. The marginal spots of the forewing very thin at the distal margin, but broad towards the disc. The 1. spot of the band of the hindwing above and beneath very thin, the 2. broader than long, broader anteriorly than posteriorly, the 3. about as long as broad, irregularly rhomboidal, the 4. and 5. long; at least the posterior 5 submarginal spots well developed above, the anal one red, some only of the marginal spots indicated or all quite small; beneath the submarginal spots large, all considerably larger than the 1. discal spot, the marginal spots in the 2 Borneo specimens larger than above; the marginal teeth strongly projecting. Mantanani Islands (North Borneo), *ledebouria.* Baram River and Lawas in Sarawak (Borneo). — **ledebouria** *Eschsch.* From Balabac, Palawan, the Philippines, Palau and Yap. ♂: the 1. discal spot of the hindwing above rounded, usually longer than broad; in the specimens from Balabac and Palawan all the spots of the band are separated by black veins, whilst in the examples from the Philippines the spots, at least in large specimens, as a rule touch one another. *horsfieldi.* The ♀ in three forms: ♀-f. **horsfieldi** *Reak.*, similar to the ♂; the 1. discal spot of the band of the hindwing much smaller than in the ♂, transverse, always larger than the submarginal spots (also beneath), the latter above never very distinct, with the exception of the red anal spot, also beneath always thinner than in the *praxilla.* preceding form; singly on all the islands. ♀-f. **praxilla** *form. nov.* (= ledebouria *Fldr.* nec *Eschsch.*), hindwing with large white discal area, the longitudinal veins traversing it not black, tail spatulate (according to SEMPER sometimes short and not widened at the apex); on all the islands with the exception of Balabac, Palawan and Palau; commonest during the rainy season; on Luzon transitions to the following form are *elyros.* common. ♀-f. **elyros** *Wall.* flies on Balabac, Palawan and Luzon, and is said to occur also on Mindoro; hindwing without white markings or these small; distinguished from ♀-f. *theseus* from Borneo and Sumatra *perversus.* chiefly by the much broader and sharper black stripes and lighter whitish stripes of the forewing. — **perversus** *Rothsch.* (33 b). A large form from the Talaut and Sangir Islands (and Siao?). ♂: the contour of the forewing recalling *P. p. alcindor* from Celebes; the costal margin more strongly curved than in *ledebouria*, the marginal spots larger. The abdominal margin of the hindwing longer than in *ledebouria* and the sub-

marginal spots of the under surface more widely separated from the distal margin; the band from the 3. spot mostly narrower than in *ledebouria*, the 2. spot at least half as long again towards the costa as posteriorly, distally cut off very obliquely, the 1. spot above large, beneath always shortened to a transverse patch; one of our specimens has on the under surface blue scales outside the posterior spots of the band. The ♀ in two forms: ♀-f. **martius** *Rothsch.*, similar to the ♂; on the hindwing the submarginal spots are absent above except for a small anal spot, but are all large beneath. ♀-f. **atavus** *Rothsch.*, similar to ♀-f. *praxilla* from the Philippines, the costal margin of the forewing more strongly curved, the black stripes narrower, the white marginal spots mostly formed as in the ♂ and sometimes almost as sharply developed; the white area of the hindwing as in ♀-f. *praxilla*, but the cell-spot usually only indicated above. — **alpheios** *Fruhst.* On the northern peninsula of Celebes in place of *alcindor* occurs a form very similar to *P. pol. ledebouria*, which was long ago recorded from there by SEMPER and OBERTHUR under the name of *alphenor*. The ♂ differs from *perversus* by the broader wings, smaller marginal spots of the forewing and narrower band of the hindwing, and from large *ledebouria* by the more distinctly separated patches of the band of the hindwing. Only the *polytes*-form of the ♀ is known: larger than the largest specimens of the Philippine ♀-f. *praxilla*, the black stripes of the forewing beneath somewhat thinner and the submarginal spots of the hindwing somewhat further separated from the distal margin. — **polycritos** *Fruhst.* (= falcidius *Fruhst.*), from the Sulla Islands (Mangola and Besi) and Bangkai, is not distinguishable from *alpheios* in the ♂. The ♀ similar to the ♂ has narrower wings than the corresponding ♀ from the Philippines (the corresponding *alpheios*-♀ is not known), also the patches of the band of the hindwing are more distinctly separated and the submarginal spots, which beneath are always large but mostly only feebly developed, are placed somewhat further from the distal margin: ♀-f. **zacora** *form. nov.* The 2. form of the ♀, ♀-f. **rhacida** *form. nov.*, has the stripes of the forewing purer white than in *alpheios* and *ledebouria*, the black basal area is larger, especially in the cell and beneath between the lower median and the hindmargin; at the distal margin in all our specimens (10) there are more or less distinct whitish spots, which are similar to those of the ♂; the tail is sometimes short and pointed as in the ♀ of *alphenor*; the white area of the hindwing always enters the cell. — **alphenor** *Cr.*, from the Southern Moluccas, inclusive of Buru, agrees in the ♂ almost entirely with *ledebouria*; the marginal spots of the forewing are on the whole smaller and the 1. patch in the band of the hindwing is larger above and thinner beneath. The ♀ in two forms, of which only ♀-f. **alphenor** *Cr.* (31 b) is known to me in nature. In this the tail is always shortened and never distinctly spatulate; the submarginal spots of the hindwing are in general large and are mostly placed further from the distal margin than in *ledebouria* and *polycrites*. The other ♀-form is similar to the ♂. — **nicanor** *Fldr.* (33 c ♂, 31 c ♀) is the form of the Northern Moluccas and Obi. Wings in ♂ and ♀ more rounded than in the preceding forms. ♂ with large marginal spots on the hindwing and also above distinct submarginal spots on the hindwing. In ♀-f. **manzer** *Rothsch.* the 1. patch of the band of the hindwing is smaller than in the ♂, beneath even thinner than the 1. submarginal spot; sometimes the two submarginal spots placed behind the very short stump of a tail are united on the underside into rings with the marginal spots. In ♀-f. **typicus** *Rothsch.* the spot of the white area of the hindwing placed below the 2. median is larger than in *alphenor*, especially on the under surface; sometimes the red discal spots of the hindwing are lengthened into stripes. — **nicomachus** *Fruhst.* is based on 4 ♂♂ which are said to be from Buru. The specimens are „somewhat larger than *nicanor Fldr.* from Batjan, the white discal spots of the hindwing more oblong, placed more separate". I doubt whether a form similar to *nicanor* occurs on Buru; I only know *alphenor* from there. The locality of FRUHSTORFER'S examples (duplicates bought in London) is probably incorrect, since according to the description he cannot be dealing with specimens of *alphenor*.

martius. *atavus.* *alpheios.* *polycritos.* *zacora, rhacida.* *alphenor.* *nicanor.* *manzer.* *typicus.* *nicomachus.*

P. ambrax. Very nearly allied to *P. polytes*; both sexes without tail. ♂: forewing with thin marginal spots confined to the edge of the wing; hindwing above with large white area, which always enters the cell and is much broader than the black marginal area; beneath this area is entirely absent or is replaced by rounded white-grey shadowy spots. ♀ on both wings with thin marginal spots, which are smaller than in all the *polytes*-forms; no indication of nail-head spots at the black distal margin of the forewing; hindwing beneath as in the ♂ with extremely small yellow-grey scales between the veins in the basal area; the white area of the hindwing similar to that of *P. pol. nicanor*, but the veins, especially the apex of the cell, even less black. There is no ♀-form similar to the ♂. The earlier stages as in the north-eastern forms of *P. polytes*. The larva on Citrus, especially common in March and April, sometimes in dozens together on one bush; when full-grown green, ventrally at the sides a broad stripe, which also covers the prolegs and is above edged with whitish; from this stripe, besides an anal band, branch off 3 bands of the same colour, which are not interrupted above, on the thorax in addition is placed a transverse band, laterally widened into spectacle-shape. The butterfly is very common. — **epirus** *Wall.* (31 c). ♂ above with red anal spot, beneath with more than 2 yellow-red spots; the apex of the forewing with faint grey stripes. ♀: the forewing between the 1. median and the 2. submedian with 2 white patches, of which at least the posterior one is much shorter than its distance from the distal margin. Aru Island. — **ambrax** *Bdv.* (= decebalus *Fruhst.*, mazaios *Fruhst.*, akames *Fruhst.*) (31 c). In the different districts of New Guinea and on

epirus. *ambrax.*

most of the small neighbouring islands definable subspecies do not yet appear to have been formed. It is true that in some districts both sexes are fairly constant, but the distinguishing characters occur again in other localities, sometimes at a great distance, so that there is no occasion for the erection of geographical races. The principal forms are: ♂-f. **ambrax** *Bdv.*, forewing with very thin grey lines at the apex; ♂-f. *ambracia.* **ambracia** *Wall.* (= ambracina *Fruhst.*), forewing with white apical patch; ♂-f. **conspectus** *Rothsch.*, hindwing *conspectus.* beneath with a number of grey discal spots; and ♂-f. **alticola** *form. nov.*, hindwing above with red anal spot, *alticola.* only known to me from the mountains of British New Guinea. ♀-f. **ambrax** *Bdv.* (= orophanes *Bdv.*) has grey stripes on the forewing, whilst ♀-f. **ambracia** *Wall.* (= lutosa *Fruhst.*) is white posteriorly on the disc of the forewing also above. On the island of Waigeu occurs exclusively ♂-f. *ambracia* and ♀-f. *ambracia*; on Misol and Salawatti ♂-f. *ambrax* and ♀-f. *ambrax*. In Dutch New Guinea (Dorei, Kapaur, Sekar, Humboldt Bay, etc.) ♂-f. *ambrax* greatly preponderates and the ♀♀ belong to ♀-f. *ambrax* or are transitions to *ambracia*, just as in the northern part of German New Guinea. Further to the south-east, at the Huon Gulf, in British New Guinea, on the D'Entrecasteaux Islands and Trobriand the ♂ has nearly always an apical patch (as on Waigeu) and the large majority of the ♀♀ have a white area on the forewing. Very many ♂♂ from the British district belong to ♂-f. *conspectus* (the type of which, however, came from Waigeu). The butterfly flies also on the Louisiades, but we only possess 1 ♀ from there (St. Aignan), which has on *artanus.* the forewing a rather small white area, interrupted by black veins. — **artanus** *Rothsch.* ♂: upper surface of the forewing with weak grey apical stripes; band of the hindwing narrower in the middle than in *P. a. ambrax*. ♀: forewing with white area as in ♀-f. *ambracia*; the 1. discal spot of the hindwing smaller than in that form, oblique, triangular or trapezoidal. Suer, Mefor Island in Geelvink Bay. — On Woodlark occurs *dunali.* **dunali** *Montr.* The ♂ not constantly different from specimens from New Guinea; forewing with small apical patch or thin stripes; the band of the hindwing narrower than in most examples from the main island. ♀: forewing with rather small white area, which is more or less strongly dusted with black; the white area of the hindwing mostly distinctly suffused with yellow, the cell-spot and the spot placed before the 2. radial *egipius.* small or absent. Similar ♀♀ also occur at low elevations at Redscar Bay in British New Guinea. — **egipius** *Misk.* (31 d) flies in Queensland. ♂: forewing with apical patch. The band of the hindwing does not reach the abdominal margin, or the last spot is diffuse; the red anal spot is almost always present also above, beneath all the submarginal spots are commonly developed. ♀: forewing with white area, the light stripes in the apex of the cell and on the disc purer white than in ♀-f. *ambracia*. Hindwing also above with a complete row of red submarginal spots.

P. phestus. The subcostal of the hindwing branches off from the cell at a greater distance from the base than in *P. ambrax*. Palpi black or with a little white scaling. ♂: similar to *P. ambrax*, but the hindwing beneath always with pure white discal spots and above always with a rather large red anal spot. ♀: forewing as in the ♂ without white marginal spots or these extremely small. The white area of the hindwing smaller than in the *ambrax*-♀ and purer white than in those specimens of *ambrax* in which the white area is reduced; the veins intersecting it always black. Larva similar to that of *ambrax*, but according to Ribbe's figure the abdominal bands are interrupted above as in the western forms of *polytes*, and the longitudinal stripe is grey with blackish bordering. On Citrus. The butterfly is rather common. Bismarck and Solomon Islands, but from the southern islands of the latter group (Guadalcanar, Maleyta and S. *parkinsoni.* Christoval) *phestus* is not known. — **parkinsoni** *Honr.* ♂: the white band of the hindwing above broad, beneath on the contrary the discal spots reduced in number and size. The ♀ with large white patch on the *minor.* forewing. Small examples of both sexes are ab. **minor** *Honr.* New Pomerania (= New Britain). — **phestus** *phestus.* *Guér.* (= nusaliki *Ribbe*) (33 c). ♂: the 4. patch of the band of the hindwing above usually strongly produced; beneath the hindwing bears 5 or 6 white spots, of which the 3. is at least as long as its distance from the distal margin. ♀: the grey stripes of the forewing are not widened into a white patch. New Mecklen- *minusculus.* burg (= New Ireland) and New Hanover. There are also here large and small specimens. — **minusculus** *Ribbe.* The ♂♂ from the Solomon Islands have usually the band on the hindwing narrower and also more deeply incised and the veins are mostly thinly but distinctly black. In specimens from the northern islands, namely Bougainville, Alu, Treasury and Choiseul (and Isabel?), the white discal spots of the under surface are mostly reduced as in *parkinsoni*; on the other hand these spots are as large as in *phestus* in examples from the islands of the Rubiana Group (Rubiana, New Georgia, Guizo, Vella Lavella, Kulambangra). The ♀ very similar to the *phestus*-♀, the veins in the white area of the hindwing above more distinctly black.

Aegeus Group.

Large tailless species. Body as in the two preceding groups black, with faint white markings on head, thorax and the underside of the abdomen, or in certain ♀♀ the abdomen above yellow and beneath black. ♂: wings black, with white band or white discal area on the upper surface of the hindwing. ♀ similar to the ♂ or mimetically modified.

P. aegeus. Without tail. Palpi laterally white. ♂: forewing as a rule with white macular band between cell and apex; on the hindwing above a broad white band, which is distally emarginate between the veins and hence dentate at the veins; on the under surface of the hindwing the band replaced by a row of grey lunules, often reduced or absent, at the distal side of which blue spots are placed; submarginal spots red or yellow, above mostly only the anal spot present and even this often absent. The ♀ in many places occurs in only one form, whilst in other districts it is polymorphic. Brown-black, always much paler than the ♂, forewing posteriorly on the disc never with thin white stripes as in the ♀ of *P. phestus* and *ambrax* and in the mimetic ♀♀ of *P. polytes*. In the normal *polydorina*-form, which occurs everywhere, a large patch in the apex of the cell of the forewing and a row of large patches on the disc are white with brown dusting; the hindwing has a white (sometimes yellowish) discal area, at the distal side of which on the under surface blue angular spots are placed. In a second form the forewing is entirely black-brown and has an oblique white macular band as in the ♂. This band is sometimes entirely absent above. Finally in the *tenarides*-form both wings are for the most part white, or the forewing is grey and the hindwing from the base to beyond the apex of the cell white; the hindwing has basally to the submarginal spots black patches, on which blue spots are placed. The young larva of the colour of bird-droppings, on the 2. to the 4. segment with 3 pairs, on each of the other segments with 1 pair of rough spines, which are also retained in the full-grown larva; the latter grey-green, with irregular, light longitudinal stripes, behind the 4. segment a black belt, which is laterally lost in a broad black-brown lateral stripe, in the middle of the body a black oblique band which terminates at the subdorsal spine, and behind it a shorter black transverse stripe; at the outer side of the prolegs and above them a black longitudinal stripe consisting of lines; head black. On Citrus. The pupa varies according to its surroundings, above in the middle yellow, the dorsum at the base of the abdomen rather strongly incurved; thoracic horn scarcely as strongly produced as the truncate horns on the head. The butterfly emerges early in the morning. It is found in gardens and in open woods, where it is commonly taken feeding at flowers, it also drinks at the edges of brooks and at wayside puddles. The flight is somewhat irregular but swift; when the butterfly scents danger it hastens away with great speed. — **aegeus** *Don.* (♂ = erectheus *Don.*) (23 c). A very common butterfly in the gardens and bush of Queensland and New South Wales, which extends southwards to Victoria and is observed even in the streets of the towns. ♂: forewing always with subapical band; the band of the hindwing touches the cell or is somewhat separated from it, frequently there is a small spot in the apex of the cell, the band does not extend beyond the lower median; at the distal side of the two last patches of the band in fresh specimens there are grey spots; the red anal spot large, round; beneath a complete series of red submarginal spots, sometimes also above several submarginal spots. The ♀ except in the northern part of its range monomorphic (*polydorina*-form): the distal half of the forewing lighter, the distal margin narrowly blackish; the submarginal spots of the hindwing above and beneath darker red than in the other races, the white discal area at least beneath extended to the costal, but the first patch usually narrow; the blue discal spots large. At Cape York and the islands off it there is also a *tenarides*-form, ♀-f. **beatrix** *Waterh.*, which is chiefly distinguished from the corresponding ♀-f. *onesimus Hew.* from New Guinea by having the white area of the hindwing beneath constantly connected with the costal margin by a white spot. — **adrastus** *Fldr.*, from the Banda Islands; the butterfly is common even on the highly cultivated ground of Great Banda. ♂: the bands of both wings similar to those of *aegeus*, the distal spot of the band of the forewing not so near to the margin; the 2. patch in the band of the hindwing at most as long as its distance from the margin, rarely a small spot is placed in the cell, the red anal spot is at least indicated above; beneath a complete row of red-yellow submarginal spots is rarely present and in this case some at least of the spots are small, mostly only the anal spot is developed. ♀ dimorphic; ♀-f. **priasa** *form. nov.*, forewing with an oblique row of 5 yellowish patches between cell and subcostal fork, the cell-spot absent above, indicated beneath. Hindwing with small, diffuse yellowish discal area, which reaches neither the subcostal nor the 2. median and is at most 8 mm. broad; the cell-spot is absent or very small. ♀-f. **tellias** *form. nov.*, forewing with light patches in the cell and on the disc, the anterior discal patches more sharply expressed than in the *polydorina*-form from New Guinea, the posterior ones sharply rounded basally and usually densely dusted with blackish; the white area of the hindwing smaller than in New Guinea specimens, with the penultimate patch twice as long as broad, the blue spot placed distally to it small, sometimes scarcely indicated, the submarginal spots all well developed, the 5. and 6. above always smaller than the 3. and 4.; the marginal spots large, which is also the case in ♀-f. *priasa*; beneath a white discal spot is commonly placed behind the costal. The ♀ figured by Felder with the locality „New Guinea" shows the characteristics of the Banda specimens and doubtless also came from Banda. — **goramensis** *Rothsch.* (♀ = ? polydorina *Haase*). ♂: the band of the forewing as in *adrastus* always well developed, distally to it neither above nor beneath distinct grey stripes; the band of the hindwing much broader than in *adrastus*, always entering the cell and posteriorly extending somewhat beyond the 2. median, measured in the middle the 2. to 4. patches are at most as long and the 6. patch somewhat more than half as long as their respective distances from the distal margin. ♀: only the *polydorina*-form known, [1]) which approximates to the corresponding form from Key; the cell-spot of the forewing

aegeus.

beatrix.

adrastus.

priasa.

tellias.

goramensis.

[1]) Wallace, Trans. Linn. Soc. XXV. t. 3. fig. 3, figures a ♀ which is said to be from Waigeu, but agrees very well with the Goram specimens. Fig. 4 of the same plate represents a white ♀ with the locality Goram; there

larger and like the discal spots tinged with yellowish and strongly brownish above; the posterior discal spots longer than in *keianus* and the veins separating them less broadly black. The marginal spots of the hindwing yellowish, the white cell-patch beneath about is large as the yellow-red anal spot or smaller,
kissuanus. above larger than beneath. Goram Laut and Manovolka. — **kissuanus** *Rothsch.* The ♂ resembles that of *goramensis*, but the band of the hindwing as somewhat broader. The light patches of the forewing in the ♀ are still more strongly brownish than in *goramensis*, the cell-spot is much smaller, the veins are more broadly black, the discal area of the hindwing is more distinctly suffused with yellow, the 1. patch of this
keianus. area is on the whole smaller and the marginal spots are larger. Kissoei, Watubela Islands. — **keianus** *Rothsch.* ♂: the subapical spots of the forewing diffuse and much smaller than in the preceding forms; the band of the hindwing always enters the cell, but never extends beyond the lower median; the red anal
amaranta. spot is nearly always present above though often weakly developed. The ♀ in two forms: ♀-f. **amaranta** *Rothsch.* is the *polydorina*-form, the light patches of the forewing at least on the under surface chalky white, the posterior ones strongly rounded basally and beneath also mostly rather sharply defined distally; the mar-
blanca. ginal spots of the hindwing larger than in the following subspecies. The light ♀ is ♀-f. **blanca** *Rothsch.*, similar to the lightest examples from New Guinea, the marginal spots of both wings larger and the isolated black discal spots of the hindwing nearer to the cell. Key Islands, according to H. Kühn rather rare; the
othello. ♀-f. *blanca* „flies only at the end of the rainy season". — **othello** *Grose-Smith.* A small form, of which only 3 specimens are known. ♂: forewing without subapical band, only beneath slight traces of it present; the band of the hindwing narrow, the patch placed behind the 2. median thin, the cell-spot small (the band has become yellow through discoloration, which is also the case in our only Biak example of *P. ambrax* from
desdemona. the same collection). The ♀ in 2 forms: ♀-f. **desdemona** *form. nov.*, patches of the forewing also above almost pure white, the cell-spot rounded, the last two discal patches elliptical, all sharply defined distally, especially on the underside; the veins in the distal part of the band of the hindwing less black than in *ormenus*, the submarginal spots above small, dusted with black, the 5. and 6. very small or absent, beneath smaller
thuria. than the preceding ones. No similar ♀ from other localities is known to me. ♀-f. **thuria** *form. nov.* is very similar to the lightest specimens from New Guinea, perhaps not constantly different; the 1. and 2. submarginal spots of the hindwing beneath narrow, as deep yellow-red as in ♀-f. *desdemona*, not present above, before the abdominal margin a thin black transverse patch with a blue streak, before this 3 separated black patches, of which the anterior one is shadowy above, the marginal tooth at the 3, radial projects very
aegatinus. distinctly. Biak, in Geelvink Bay. — **aegatinus** *Rothsch.* Likewise small. ♂: forewing with 2 or 3 very small subapical spots or none at all; band of the hindwing touching the cell, only entering it in one of the 8 specimens before me; beneath the hindwing has a complete row of blue discal spots, which are mostly large and at the proximal side of which there is not a trace of grey spots. The ♀ in 2 forms (it may be
melia. assumed that in addition a *tenarides*-form also occurs): ♀-f. **melia** *Rothsch.*, forewing above entirely brown, with a slight indication of 3 grey spots distally to the apex of the cell, these spots beneath somewhat more distinct, the middle one in the subcostal fork; the discal area of the hindwing basally rounded, with very small cell-spot, posteriorly scarcely reaching the 2. median; the red submarginal spots above thin, with the exception of the anal spot, beneath a row of 5 white discal spots is present, which are all remote from the cell and of
myrtis. which the first is very small. ♀-f. **myrtis** *Rothsch.*, the patches of the forewing beneath white and sharply defined, above very strongly blackened, the cell-patch transverse, beneath about three times as long as broad, the posterior discal patches more or less reduced, no whitish spot behind the submedian; only the posterior yellow submarginal patches of the hindwing above developed, beneath the 2. to 6. narrow, almost straight, and nearly equal in size, the white area as large as in normal New Guinea specimens, the spot placed behind the 2. median small.
ormenus. Mefor (= Mafoor) in Geelvink Bay. — **ormenus** *Guér.* (= ormenulus *Fruhst.*, aegates *Fruhst.*). The ♂ in two forms connected by transitions: ♂-f. **ormenus** *Guér.* (23 c), with a subapical band of large white spots on the
pandion. forewing, and ♂-f. **pandion** *Wall.*, with a band of small spots or entirely without band. The two forms do not everywhere occur together; on Aru there are only and on Waigeu almost only large-spotted specimens; in the intermediate districts: Misol, Salawatti, and Dutch New Guinea, and also on Jobi and everywhere in the north of Dutch and German New Guinea occurs almost exclusively ♂-f. *pandion*; at Huon Gulf and in British New Guinea on the contrary *pandion* is the exception and is almost entirely wanting on the islands to the east and south-east of British New Guinea, at least we only possess more or less large-spotted specimens from there. As a rule the band of the hindwing is broader behind the 2. median in ♂-f. *pandion* than in ♂-f. *ormenus*, but the difference is not at all constant. Also the ♀ has not yet developed geographical differences which recur in the majority of the specimens from any single locality. The principal forms are:
inornatus. ♀-f. **inornatus** *Rothsch.* (25 a). Forewing above entirely brown, beneath with whitish spots distally to the cell; hindwing with the white discal area reduced, especially beneath; only known to me from the Arfak Pe-
selcucis. ninsula and Yanarba Island, to the south-east of British New Guinea. ♀-f. **seleucis** *form. nov.*, forewing brown, with a subapical row of 5 spots, which are arranged as in the ♂ and of which the second is placed in the subcostal fork; discal area of the hindwing as in the preceding ♀ beneath widely separated from the

---

is possibly a confusion in the locality of the two ♀♀. Haase gave fig. 3 the name *polydorina*, which we retain as a suitable designation for all the ♀♀ of *P. aegeus* which recall *P. polydorus*.

cell; only known to me from Waigeu. ♀-f. **timoxena** *form. nov.*, like the preceding, but the spots of the fore- *timoxena.*
wing are placed between the cell and the subcostal fork and thus correspond to the light patches surrounding the apex of the cell in the *polydorina*-form; the white area of the hindwing beneath not always strongly reduced; only known to me from Trobriand. Transitions from this form to the next I know from Waigeu, Etna Bay (Dutch South-West New Guinea) and Trobriand. The form which is common everywhere and may be regarded as normal I call ♀-f. **leporina** *nom. nov.* (the name *polydorina Haase* most probably refers *leporina.*
to the corresponding ♀-form from Goram), forewing lighter in the distal half, always with cell-patch, the light parts above usually more or less strongly brownish, beneath mostly pure white (or almost); hindwing with large white area, which anteriorly reaches the subcostal, distally to the 4. and the 5. patch a blue spot (often large), the anterior submarginal spots sometimes not developed, as a rule the 6. larger than the preceding ones. The light, *Tenaris*-like ♀♀ are: ♀-f. **amanga** *Bdv.* (= intermedia *Hag.*) (24 b), forewing entirely grey- *amanga.*
brown, hindwing for the most part white, with broad dark distal margin and yellow anal area; probably occurs everywhere, known from Waigeu, Huon Gulf and British New Guinea (Aroa River, in low situations). ♀-f. **onesimus** *Hew.* (= tenarides *Hag.*), both wings for the most part white; very variable in the details *onesimus.*
of the marking on the hindwing; everywhere, but rarer than ♀-f. *leporina*. The area of distribution of *ormenus* embraces the whole of New Guinea, Waigeu, Salawatti, Misol, Jobi, the D'Entrecasteaux Islands, Trobriand, Woodlark, the Louisiades and the Egum Group. — Lately ♂♂ from German New Guinea (Astrolabe Bay) with lemon-yellow band on the hindwing have been described as a separate species, **pan-** *pandoxus.*
doxus *Grose-Smith.* As in the same collection (sent by Wahnes) there was also a ♂ of *P. ambrax* with similarly coloured band, I infer that discoloration occurred after the death of the butterfly. The scales are normal. — **websteri** *Gr.-Sm.* ♂: the subapical spots of the forewing of medium size, always present, *websteri.*
the row sometimes continued almost to the hindmargin by small indistinct spots (in *ormenus* there are also in single specimens small white spots before the hindmargin); the band of the hindwing broad, the first patch not widened basally, the inner margin of the band consequently uniformly rounded from the costal to the 2, median. The ♀ in 2 forms: ♀-f. **sopaea** *form. nov.* resembles the ♂; forewing with curved sub- *sopaea.*
apical band of medium-sized spots; the white area of the hindwing smaller than in the ♂, anteriorly only extending to the subcostal, beneath remote from the cell. ♀-f. **bismarckianus** *Rothsch.*, forewing with a *bismarckianus.*
curved band of large discal patches from the costa almost to the anal angle, the upper patches close to the cell, the latter with apical patch, which above is narrow or entirely wanting; the white area of the hindwing on both surfaces large, usually a thin white transverse patch is placed behind the costal. New Pom-
erania (= New Britain). — **oritas** *Godm. & Salv.* The apex of the forewing less rounded. ♂: the sub- *oritas.*
apical band of the forewing much broader than in *websteri*, the white band of the hindwing proximally almost straight or the 1. patch distinctly prolonged basad, the patch placed behind the 2. median large. The ♀ in 2 forms: ♀-f. **ximene** *form. nov.* resembles the ♂, band of the forewing broader than in *websteri*; *ximene.*
the area of the hindwing above large, extending from the subcostal to the 2. median or beyond it, beneath entirely obsolete or represented by grey-yellow discal nebulous spots. ♀-f. **nymphasia** *form. nov.*, the patches *nymphasia.*
of the forewing less sharply defined than in ♀-f. *bismarckianus*, more brownish, the cell-patch larger; the hindwing with longer tooth at the 3. radial and with paler submarginal spots. New Mecklenburg (= New Ireland) and New Hanover.

P. tydeus. Differentiated from all the forms of *P. aegeus* by the large ochre-yellow submarginal spots of the hindwing, which are distally truncate or emarginate and proximally are produced along the veins into bracket-like projections. ♂ always with subapical oblique band of white spots; the band of the hindwing narrow, not touching the cell, the 1. patch prolonged almost to the base. The ♀ appears only in the *tenarides*-form: forewing lighter in the centre; hindwing from the base to the disc yellowish white, at the proximal side of a broad discal band of large, black, connected patches ochre-yellow; the base of the costal margin beneath broadly black. Only on the Northern Moluccas. — **tydeus** *Fldr.* flies on Morty, *tydeus.*
Halmaheira, Ternate and Batjan. ♂: the spot placed behind the subcostal fork on the forewing shorter than its distance from the cell. ♀: the cell-spot of the forewing beneath reaches the base of the lower median; at the innerside of the 1. black discal spot of the hindwing beneath is placed a thin, often very diffuse, yellowish transverse spot. — **obiensis** *Rothsch.*, from Obi. ♂: the subapical band of the forewing broader than *obiensis.*
in *tydeus*, the 4. spot longer than its distance from the cell. ♀: both wings more extended light; the cell-spot of the forewing beneath extends to beyond the base of the 2. median; the transverse spot placed at the innerside of the 1. black discal spot of the hindwing beneath is produced basad along the subcostal.

P. gambrisius. Perhaps not specifically different from *P. aegeus*. Palpi less white. ♂: forewing with 4 subapical spots, the 1. and 2. small, sometimes absent, these spots beneath mostly much smaller than above. The band of the hindwing as in *P. aegeus* anteriorly widened basad, at the distal side of the 5. and 6. patches more or less strongly developed grey nebulous spots, the 5. patch at most half (usually only $^1/_3$) as long as its distance from the distal margin; beneath the hindwing bears a row of blue discal patches and proximally to them grey spots. ♀ monomorphic: forewing with large cell-patch and long discal patches. Hindwing with yellowish white, posteriorly ochre-yellow median band, which always reaches the costal and is broader posteriorly than between the costal and the cell; distally to the band large blue spots.

The earlier stages not known, probably very similar to those of *P. aegeus*. A butterfly of the open woods with a profusion of undergrowth, among which it flies about with great rapidity; it drinks at puddles and
gambrisius. the edges of brooks. Southern Moluccas. — **gambrisius** *Cr.* (♀ = drusius *Cr.*, fusconiger *Goeze*, drimachus *Godt.*; ♂ = amphitrion *Cr.* artefact; ♂♀ = colossus *Fruhst.*) (24 b). ♂: under surface of the hindwing with
abbreviatus. small yellow-red anal spot, without submarginal spots. ♂-ab. **abbreviatus** *Rothsch.*: band of the hindwing only reaching the 2. median; from Amboina in coll. Oberthur (ex coll. Boisduval). Fruhstorfer's *P. aegeus*
oritinus. **oritinus,** which was described from a specimen without locality, is perhaps an aberrant starveling of *gambrisius* with exceptionally large grey discal patches on the underside of the hindwing. According to Fruhstorfer ♂♂ from Ceram have a much larger and ♀♀ a much smaller cell-spot on the hindwing than examplee from Amboina, which is not confirmed by our specimens. ♀: the 3.—5. spots of the band of the hindwing shorter than the 1. and 2. spots. Amboina, Saparoea, Ceram. Rare; collectors obtain but few specimens;
buruanus. the insect easily eludes pursuit by its swift flight. — **buruanus** *Rothsch.* ♂: apex of the forewing strongly striped with grey, the subapical spots mostly larger than in the preceding form. The band of the hindwing narrower, the yellow-red anal spot on the underside of the hindwing large, also several yellow-red submarginal spots are present. ♀: the 1. and 2. spots in the band of the hindwing shorter and the 3.—5. longer than in *gambrisius*, the yellow-red submarginal spots above and beneath sharply developed. Buru, at the coast and in the mountains.

P. inopinatus. Nearly allied to *P. aegeus*. ♂: forewing with broad, white subapical band, which extends from the costal margin to the 3. radial and touches the upper angle of the cell. The band of the hindwing similar to that of *P. aegeus*, the 4. patch the longest, about as long as its distance from the distal margin, the 6. thin, posteriorly pointed, often not reaching the 2. median, behind this vein no white spot; the yellowish red anal spot above always present, beneath in addition one or several submarginal spots developed, the white cell-spot small or absent. ♀ in one form: forewing with broad white or somewhat yellowish band from the middle of the costal margin to the hinder angle; hindwing black, above without discal spot, but with large red submarginal spots, beneath with very narrow diffuse brownish yellow or whi-
inopinatus. tish discal band, which is remote from the cell. The earlier stages unknown. — **inopinatus** *Btlr.* (24 a), from different islands of the Tenimber Group. The anal spot of the hindwing in the ♂ and the submarginal
kosmos. spot of the upperside of the hindwing in the ♀ red. — **kosmos** *Fruhst.* (= inauris *Fruhst.*). The submarginal spots of the hindwing somewhat more yellowish (faded after death in the tropical climate?) and the marginal spots on the whole somewhat larger; none of the other differences given by Fruhstorfer are tenable. Babber, Dammer and Roma.

oberon. **P. oberon** *Gr.-Sm.* (23 c). Nearly allied to *P. aegeus*. ♂: forewing with rather broad, straight macular band; the band of the hindwing reaches the 2. median, the red anal spot is large; beneath the hindwing has a complete row of large red submarginal spots and from the anal patch forwards a number of yellowish white discal spots. ♀: forewing above with some somewhat diffuse spots distally to the apex of the cell; these spots beneath developed into a broad band, which touches the apex of the cell and runs from the costal to the 3. radial; on the under surface a small angular spot in the cell and a larger white spot before the anal angle. Hindwing above with small yellowish white discal area from the subcostal nearly to the abdominal margin, consisting of 7 spots (including the cell-spot), beneath the area developed into an anteriorly and posteriorly thin band, which reaches to the costal and touches the cell; the red submarginal spots large on both sides. — On the Santa Cruz Islands.

P. bridgei. The sexes very different. ♂ black as in *P. aegeus*, forewing with macular band from the costal to the hindmargin, or with subapical band and a patch placed before the hindmargin. The white band of the hindwing formed as in *P. aegeus*, i. e. the 1. patch prolonged basad; beneath the hindwing has red-yellow or reddish grey submarginal and blue discal spots. The ♀ corresponds to the *polydorina*-form of *P. aegeus*; the patches white or yellowish, the submarginal spots of the hindwing sometimes yellow-red; the forewing with large cell-spot, which is remote from the apex of the cell, and a band of discal patches which are separated by broad brown-black vein-stripes and of which the 3 posterior ones are placed much further from the distal margin than in *P. aegeus*; the hindwing with large cell-spot and 6 patches placed round the cell, which are distally rounded and all closely approximated to it, the 1. spot sometimes indistinct or obsolete. Larva very similar to that of *P. aegeus*, green, with irregular, short light longitudinal streaks, black head, black legs and above them a broad black longitudinal stripe, from which 4 bands emanate, on the 4., 7., 9. and last segments; the spines as in *P. aegeus*; on Citrus, in the forest. Pupa as in *P. aegeus*, in proportion to its size somewhat more slender. The butterfly in woods, where it is not easy to catch on account of the thick undergrowth and its swift flight. Appears to occur on all the islands
bridgei. of the Solomon Group, but is not yet known from Maleyta. — **bridgei** *Math.* (= fischeri *Ribbe*, nobilior *Fruhst.*, togonis *Rothsch.*). Our large series of specimens shows that only one form flies on the islands from Bougainville to Isabel; the differences given for the specimens from the various islands prove to be quite unreliable. The submarginal spots of the hindwing beneath in ♂ and ♀ large, at least the posterior ones broader than or as broad as the black border separating them from the marginal spots. Ribbe has named

yellowish ♀♀ ab. **gorei.** Bougainville, Fauro, Alu, Treasury, Choiseul and Isabel. — **ortegae** *Rothsch.* A transitional form to *hecataeus.* Submarginal spots of the hindwing beneath in the ♂ small, narrower than the black border separating them from the marginal spots, the anterior spots of the forewing larger than in the preceding form, sometimes all the spots except the last two very small. In the ♀ the marginal spots of the forewing and the submarginal spots of the hindwing smaller, the marginal spots of the hindwing on the contrary somewhat larger than in *bridgei.* Florida and Gela. — **hecataeus** *Godm. & Salv.* (25 a). ♂: the 5. and 6. spots of the forewing always much smaller than the preceding spots, which are larger than in *ortegae* and *bridgei* and also beneath large and sharply defined. ♀: the marginal spots of the forewing beneath smaller than in the other forms, none of the admarginal spots being distinctly developed, whilst the latter in *ortegae* and *bridgei,* but especially in *prospero,* are merged together with the marginal spots into nailhead-patches; the 4. discal spot of the forewing, reckoning from behind, dot-like or at most as large as the 3. On Guadalcanar. — **tryoni** *Math.* ♂: the band of the forewing consists of 5 spots; the hindwing has some submarginal spots above. ♀: hindwing above and beneath with yellow-red submarginal spots. Ugi and San Cristoval; 1 ♂ in coll. GODMAN, 2 ♀♀ in the Tring Museum. — **prospero** *Gr.-Sm.* (24 a). The most aberrant form (cf. *P. woodfordi laarchus*). ♂: forewing with subapical band and before the hindmargin one or two patches, sometimes a few more spots are slightly indicated between the band and these patches, which correspond to the posterior spots of the band of the preceding forms; band of the hindwing very broad, with long teeth; on the under surface of the hindwing the anterior submarginal spots are wanting. ♀: on the forewing above and beneath admarginal spots which form nailhead-patches with the marginal spots; the submarginal spots of the hindwing very large, strongly emarginate distally, especially above. On New Georgia and the neighbouring islands: Kulambangra, Guizo, Rendova, Vella Lavella.

gorei. ortegae. hecataeus. tryoni. prospero.

P. woodfordi. Sexes similar, the ♀ somewhat paler. Forewing above with complete broad white discal band or only with white spots between cell and apex. On the upper surface of the hindwing a white discal band which extends from the costal to the abdominal margin and is almost straight proximally, the 1. patch of the band always smaller than the 2., commonly much shorter than the 7.; the marginal tooth of the 3. radial distinctly projecting. On the under surface of the forewing a subapical band, which is commonly reduced to some faint spots. The hindwing beneath with submargianl spots, of which above mostly only the anal spot (sometimes also a second one) is developed; on the disc blue spots and proximally to these frequently a grey macular band. Northern Solomon Islands. The larva on Citrus; green, the underside with the exception of the thorax grey-green, on the raised 4. segment a black belt, which laterally is produced into a point anteriorly; on the pronotum and the 11. segment a pair of pale spines. — **woodfordi** *Godm. & Salv.* (23 b). Forewing with a band running from the costal to the hindmargin, which is more or less interrupted below the 2. radial. ♀♀ with yellowish bands are ab. **ochracea** *Ribbe.* Bougainville and Shortland Islands (Alu, Fauro). — **choiseuli** *Rothsch.* (24 b). The band of the forewing only developed in the anterior part, which is placed close to the apex of the cell. Choiseul. — **ariel** *Gr.-Sm.* Forewing in the ♂ with 2—4, in the ♀ with 3—5 spots, which are separated from the cell, posteriorly on the disc commonly traces of white spots; the band of the hindwing narrower than in the two preceding forms. Isabel. — **laarchus** *Godm. & Salv.* (23 b). Forewing with an oblique subapical band remote from the cell, terminating before the 2. radial half-way between cell and distal margin and appearing again before the hindmargin in the form of diffuse spots. The band of the hindwing almost twice as broad as in *ariel.* Rubiana Group: New Georgia, Kulambangra, Vella Lavella, Guizo, Rendova; common. The butterfly has a swift flight like all the allied species; it occurs principally in the open forest with much undergrowth, but also flies in the thick primeval forest.

woodfordi. ochracea. choiseuli. ariel. laarchus.

P. ptolychus *Godm. & Salv.* (23 b). Forewing with a curved band between cell and apex and a row of 3 or 4 submarginal spots from the hindmargin to the 2. or 3. radial. The band of the hindwing much narrower than the black marginal area, curved, rarely entering the cell. The ♀ paler than the ♂, hindwing above often with submarginal spots. — Guadalcanar and Florida.

ptolychus.

P. erskinei *Math.* ♂: forewing more rounded than in the two preceding species, above with a row of spots from the costal to the hindmargin, all the spots separated with the exception of the last three, beneath with four large, separated subapical spots. The band of the forewing touches the apex of the cell and is as broad in the middle as the black marginal area; the red anal spot large; beneath a complete row of red submarginal spots. — Ugi; only 1 ♂ known (in coll. GODMAN, now in the British Museum).

erskinei.

Memnon Group.

The wings beneath red or yellow at the base, with the exception of *P. ascalaphus* and *protenor.* ♂: upperside of the hindwing always black, never with white band, but almost always with grey or white-blue scaling, which is sometimes condensed into a broad band composed of stripes, only in *protenor* a large white costal patch present, which is hidden by the forewing. ♀ similar to the ♂ or with white, yellowish or reddish discal area or band on the hindwing, mimicking Aristolochia-Papilios.

P. ascalaphus. Underside of the body almost without traces of grey-white longitudinal lines; palpi with white spot, both sexes tailed and above and beneath without patches at the base. ♂: forewing with yellowish grey, hindwing with grey-blue or yellowish grey stripes before the distal margin; beneath the stripes of the forewing more discally placed, those of the hindwing replaced by much shorter grey-blue discal spots, distally to which are placed yellow submarginal spots, more or less shaded with blue. The ♀ very different from the ♂; the forewing from the base to about the 2. median black, then follows a large, posteriorly narrowed central white area, which is intersected by black stripes, the distal margin again broadly black; hindwing with large white central area, interrupted by the veins, which in a second ♀-form is only indicated by indistinctly defined grey and bluish patches; the red-yellow submarginal spots, with white tips, are well developed above and beneath. The earlier stages not described. The yellow egg is laid on Citrus, on which the larva lives. The butterfly is very common, especially in lower elevations near the coast. It is frequently found at Papaja flowers. „The ♀♀ are also fond of hiding in the foliage of Citrus trees and fly about
ascalaphus. even in the gardens and streets of Macassar" (FRUHSTORFER). — **ascalaphus** *Bdv.* (33 a), from Celebes. ♂: on the upper surface of the hindwing with broad grey-blue band composed of stripes. The ♀ bears normally a large white discal area on the hindwing; but sometimes specimens also occur in which this area
nubiger. is replaced by indistinct, blue-dusted grey patches: ♀-ab. **nubiger** *Fruhst.*; this darkened form is only known
ascalon. to me from North Celebes. — **ascalon** *Stgr.* (28 a). ♂: the stripes on the upperside of both wings short and yellowish, on the hindwing much less prominent than in *ascalaphus*. In the ♀ the middle of the forewing and the discal area of the hindwing are purer white than in *ascalaphus*. Sulla Islands: Mangola.

P. oenomaus. Black, tailed, entirely without blue scaling, the forewing elongate. ♂: forewing parallel with the distal margin with broad discal band which is pale yellow above, grey-white beneath; hindwing above without markings, beneath with a single row of yellowish red submarginal spots, which are remote from the cell and are sometimes indicated above also, and with 3 red basal patches. In the ♀ the disc and cell of the forewing are semitransparent, the band is paler and the red basal patch, which in the ♂ is only present beneath, is developed above also; on the hindwing a median band, which is reddish at its edges, the red submarginal spots above and beneath large, and the marginal spots reddish. The ♀ is very similar
oenomaus. to *P. liris*, and flies together with it. — **oenomaus** *Godt.* (28 b). occurs on Timor, Moa, Kisser and Roma (most probably also on the other small islands between Timor and Tenimber). The ♀ with broad median band on the hindwing. Whilst *P. liris* is different on almost all the islands, *oenomaus* apparently shows no differences either in ♂ or ♀ on those mentioned above. On the other hand the following subspecies follows
subfasciatus. its model. — **subfasciatus** *Rothsch.* (28 b), from Wetter, is distinguished in the ♀ by a very narrow, incomplete discal band on the hindwing, just as *P. liris wetterensis*. This band is above and beneath pale red and usually interrupted before the cell, sometimes it is only faintly indicated beneath between costa and cell. The ♂♂ are not constantly different from *oenomaus*; in general they have the band of the forewing somewhat narrower.

P. polymnester. ♂: a broad, costally obsolescent discal band on the forewing and the distal $^2/_3$ of the upperside of the hindwing white-blue; this area encloses a row of black discal patches and a similar row of submarginal spots; some of the latter united with the black distal margin. On the under surface the band of the forewing more discal and the area of the hindwing reduced, especially from the base, both dirty yellow-grey. The ♀ paler than the ♂, the band of the forewing and the area of the hindwing yellowish white suffused with bluish. The full-grown larva green, with strongly swollen thorax, shiny, at the sides of the thorax a thin white lateral line and above the prolegs a broader lateral stripe; on the thorax a black-dotted spectacle-marking and behind it a raised belt marked with black and white, at the sides of the abdomen two abbreviated white oblique bands, the anal segment likewise white. Pupa brown or green, with obtuse, strongly produced horns on the head and widely expanding wing-cases. On Citrus, Atalantia, Paramigyna, etc. The butterfly especially common in the plains, but also ascends high into the mountains, and occurs all through the summer in gardens, open country and in the woods. The flight is in general slow and imposing, yet the butterfly can also dart through the air. It is often taken at flowers, over which it remains hovering; it shows itself at such times so fearless that it can be caught with the fingers. Ceylon and South India to Calcutta; north of the Ganges only single stragglers, is said also to have been seen (!)
parinda. in Burma. — **parinda** *Moore* (26 a). ♂: not constantly different from the following form; the band of the forewing broad, the stripe placed behind the 2. median longer than its distance from the cell. ♀: the band of the forewing and the light area of the hindwing yellowish, much less blue than in the ♂. Everywhere
polymnestor. in Ceylon. — **polymnestor** *Cr.* (26 a). ♂: band of the forewing usually narrower than in the preceding form. ♀: almost as blue as the ♂ or at least bluer than the ♀ of *parinda*. Distributed over the whole of South India to Calcutta, in the Tring Museum also a (migrant) ♂ from Sikkim (MÖLLER coll.) and a second from Assam.

lampsacus. **P. lampsacus** *Bdv.* (26 b). Two longitudinal lines beneath at each side of the abdomen and a broad discal band on the hindwing, produced at the veins to the distal margin, white-yellow, the anal spot of the band and a narrow basal central streak on the under surface of the hindwing deeper yellow. The ♀ paler

than the ♂, with white-yellow basal patch on the upperside of the forewing. — Java: in the mountains, at 1500—4000 ft. elevation. A mimic of the Aristolochia Papilio *P. priapus*.

P. forbesi *Gr.-Smith* (26 b). Abdomen entirely black; under surface of the hindwing with red costal patch at the base. ♂: forewing with long, strong grey stripes before the distal margin; hindwing above with some grey submarginal lunules, which vary in number, the white marginal spots large. Under surface of the hindwing with large ochre-yellow area, which extends from the anal angle to the radial veins, is remote from the cell and encloses black patches; above this area some small blue spots. ♀ paler than the ♂, the grey stripes of the forewing extend to the cell and the latter is likewise striped; hindwing with large, almost pure white area, which extends to the subcostal or the 1. radial, almost reaches the cell and encloses large black discal and submarginal patches; forewing above with yellowish white patch at the base of the cell: ♀-f. **humeralis** *form. nov.*, or without this patch: ♀-f. **nigribasalis** *form. nov.* — Only known from the mountains of Sumatra, not below 3000 ft.; flies all the year round; the ♂ common on the sand of river-banks; the ♀ very rare. *forbesi. humeralis. nigribasalis.*

P. acheron *Gr.-Smith* (= goetheanus *Fruhst.*) (27 a). Very similar to the preceding species, the stripes of the forewing much weaker, the red basal spot on the underside of the hindwing larger, the light area in ♂ and ♀ yellow and very much smaller than in *forbesi*, in the ♀ only very little larger than in the ♂; the upper surface of the hindwing in ♂ and ♀ without markings except for a row of large, shadowy discal patches consisting of scattered blue-grey scales, the marginal spots very thin. — North Borneo, in the hills (Kina Balu, Mt. Mulu, Mt. Dulit, etc.), the ♂ common. *acheron.*

P. mayo *Hew.* (♀ = charicles Hew.) (25 b). One of the most beautiful species of this group. ♂ tailless, though the marginal tooth of the 3. radial projects perceptibly; hindwing above with a densely scaled, broad light blue discal band, which mostly touches the cell and is placed at a distance from the distal margin. The posterior discal, submarginal and usually also the marginal lunules brown-red; sometimes all these red spots are absent, the anal ring is only feebly indicated, and a very conspicuous grey-blue macular band is placed on the disc. The ♀ monomorphic, a mimic of the Aristolochia Papilio *P. rhodifer*, which is common in that locality: forewing with red basal spot, the disc and cell lighter as in the ♀ of *P. oenomaus*; hindwing with large white cell-spot and an interrupted row of discal patches placed at the cell, the submarginal spots dull red, the posterior ones very large, the last prolonged into a broad stripe which reaches the white discal spot, tip of tail whitish red. Under surface as upper, the anterior marginal spots of the hindwing whitish. — Andamans, the ♂ common. *mayo.*

P. lowi *Druce* (25 b). ♂ and ♀ tailed. ♂ black, upper surface of the forewing with rather short blue-grey stripes at the distal margin; hindwing with broad, blue-grey, densely scaled band, which extends nearly to the distal margin, is almost uniformly concave towards the base and does not reach the cell. ♀ in two principal forms; forewing with the exception of the base much lighter, the red basal spot at least indicated, the blackish stripes between the veins weaker than in the *memnon*-forms, hindwing with large white, distally yellowish central area, which is intersected by the thin black veins: ♀-f. **zephyria** *form. nov.*; or the hindwing almost entirely black, without white area: ♀-f. **suffusus** *Lathy.* — Palawan, Balabac and North Borneo. *lowi. zephyria. suffusus.*

P. memnon. Palpi with 3 small white spots. Under surface of the wings with large, dull red spot at the base, which on the hindwing is divided by the veins and is often present also on the upper surface of the forewing. ♂ black, with greenish or bluish sheen, the veins of the forewing accompanied by light bluish stripes. Hindwing above likewise with grey-blue stripes, which are mostly indistinctly defined; always without tail. Under surface of the hindwing in the distal part with 2 rows of large black patches, which are surrounded by grey, grey-blue, yellowish or yellowish red scaling, often only the submarginal black patches distinct and sometimes only the posterior ones of these. The ♀ in some districts fairly constant, in others extraordinarily variable. Of these different ♀-forms only a few can be regarded as mimetic. The forewing of the ♀ is always paler than in the ♂; the hindwing above dark, often striped with blue as in the ♂, and beneath as in the ♂ with 2 rows of black patches, or the hindwing with white discal patches and beneath with only one row of black patches, which are often very large and joined together. These two principal forms tailless and extraordinarily variable individually. The form which appears to be the oldest is tailed, has on the hindwing a white cell-spot (often large) and round the cell a row of likewise white patches, the distal ones more or less yellow or dull red; similar to the white-spotted ♀ of *P. lowi*, but the veins which separate the spots more broadly black. This tailed ♀-form is wanting in Borneo and is there represented by an otherwise quite similar tailless form. The abdomen of the ♀♀ with light hindwing is often yellow at the sides. The young larva brown, anteriorly on the thorax and on each of the last two abdominal segments with a pair of light spines, which disappear later; when full-grown dark velvety green, here and there bluish, the thorax swollen, with spectacle-marking and black transverse band, before which a whitish green band is placed, at the sides of the abdomen two whitish green oblique bands, of which the first is dorsally united with the band of the other side, the tip of the abdomen and a longitudinal stripe above the legs greenish white; the scent-fork in the young larva black, afterwards red. Pupa green or brown, above between the

wing-cases yellow; horns on the head strongly projecting, the wing-cases broad, the first 3 abdominal segments above them rough, the 3. segment triangularly widened laterally. On Citrus. Dr. MARTIN has bred tailless ♀♀ from the green eggs of a tailed ♀. Distributed from South Japan and North India to Borneo and the small Sunda Islands; wanting in South India and on Ceylon, where the species is replaced by *P. polymnestor*. The butterfly is very common and occurs in the northern districts from the spring to the autumn and in the southern localities all the year round; in lower elevations, in the Himalayas up to 7000 ft. It occurs everywhere near the settlements and in open woods. The ♂ visits flowers, but is never met with on moist places on the roads; its flight is swift and restless, whilst the sluggish ♀ sails more slowly and is therefore easier to catch. — The most northerly race is **thunbergi** *Sieb*, from Kiu Shiu, whose spring form has recently been designated by FRUHSTORFER f. temp. *mela*. — **pryeri** *Rothsch.* (30 b) flies on the Loo Choo Islands. ♂: the grey-blue stripes of the upper surface narrow and the posterior stripes of the hindwing far removed from the margin. Spring specimens as in the preceding race have a red basal spot on the upper surface of the hindwing. The ♀ only in one fairly constant form: forewing with white double stripes between the veins, so that the disc, especially the posterior part, appears almost pure white with black stripes; hindwing as in the ♂ with distinctly projecting tooth at the 3. radial, with a discal row of 5—7 large white patches and sometimes some white scales in the apex of the cell, the marginal spots above scarcely indicated, with the exception of the posterior two, which are reddish. — **agenor** *L.* (♂ = androgeus *Cr.*, mestor *Hbn.*) (30 a). This subspecies, which is polymorphic in the ♀, shows charcteristic differences in every geographical district, but the totality of the individuals from one district is not separable from the totality of the examples from another, since the various districts have all some forms in common. In the normal ♂♂ the forewing above and beneath and the hindwing above are broad-striped; the under surface of the hindwing is more or less red in the anal part, sometimes this colour extends to the costal margin, rarely no red at all is present, and often there is a blue macular band on this side, sometimes some of the stripes of the forewing beneath are also glossy blue; in spring specimens of the northern districts the upper surface of the forewing has usually a red basal spot. In ab. **heronus** *Fruhst.* the stripes of the forewing beneath are reduced in length and breadth; here belong all the examples known to me from Formosa, but specimens with a similar development of these stripes are also met with in other districts. ♂-ab. **primigenius** *Rothsch.* (27 a) is an aberration recalling *P. polymnestor* by the condensation of the light blue scaling on the upper surface of the hindwing and has the black submarginal spots especially heavily margined with white-blue; only known to me from Sikkim and the Khassia Hills in Assam. Still more peculiar is ab. **polymnestoroides** *Moore* (32 c), which occurs both in ♂ and ♀: the stripes on the upperside of the forewing in the ♂ are short, those of the hindwing above are densely scaled, linear, and do not reach the distal margin or enter the cell; in the ♀ the forewing is sepia-colour, distally lighter, and the otherwise dark hindwing bears a large blue central area, extending from the subcostal to the hindmargin, which is distally produced into streaks; known from Assam (Jaintia Hills) and Calcutta. The Tring Museum also possesses transitions from this aberration to normal specimens. In ab. **depelchini** *Robbe* ♂ and ♀ are characterised by more strongly dentate hindwing, also almost all the grey-blue scaling is absent on the upper surface; the upperside of the hindwing with greenish gloss, in the ♀ with open red anal ring and very slight traces of black patches; Sikkim. Of the polymorphic ♀, besides the ♀♀ of ab. *depelchini* and *polymnestoroides*, the following principal forms are known, each of which again varies considerably in itself: all the ♀♀ have at least traces of red or yellow-red spots at the anal angle of the hindwing and always possess on the upper surface of the forewing a red basal spot. ♀-f. **rhetenorina** *form. nov.*, tailless, both wings dark sepia-colour, forewing with darker stripes between the veins, hindwing above with slight blue scaling and often red anal ring, which is sometimes replaced by a spot without black centre, usually a broad white stripe along the hindmargin beneath; North India. ♀-f. **butlerianus** *Rothsch.* (29 b), like the preceding, forewing with white area before the hindmargin, hindwing above more strongly scaled with blue; North India to Malacca. ♀-f. **esperi** *Btlr.* resembles the ♂ above and beneath, but the forewing has a large white subapical area as in the forms from Sumatra and Borneo mentioned below; only known from Malacca. ♀-f. **vinius** *Fruhst.* (= cilix *Dist.* nec *Salv. & Godm.*), forewing unicolorous, with the usual stripes, hindwing above with 2 white patches and traces of a 3., beneath without these patches; only known from Malacca. ♀-f. **phoenix** *Dist.*, forewing as the preceding, hindwing above and beneath with 4 or 5 patches, of which especially the posterior ones are often broadly red; in North Indian specimens the last spot is frequently prolonged basad and there are often black discal patches beneath, rarely a white spot is placed in the cell; Malacca to North India. ♀-f. **agenor** *L.*, larger than *phoenix*, the forewing in general somewhat lighter, sometimes almost as much striped with white as in *pryeri*, the hindwing with 5—7 white or yellowish discal patches, the posterior ones only prolonged basad in examples with very large patches, there are also no black discal spots present, not even in specimens with proportionately small white patches; the marginal spots of the hindwing more transverse than in ♀-f. *phoenix*; Formosa, China, Hainan, ? Tonkin, Burma. The following ♀♀ are tailed: ♀-f. **alcanor** *Cr.*, the cell-spot of the hindwing and sometimes also the discal patches (as in CRAMER'S figure) small, the black vein-stripes always thick; Formosa, China, North India, Burma, Tenasserim. ♀-f. **distantianus** *Rothsch.* (= achates *Cr.* nec *Sulzer*) (33 a). The cell-spot of the

thunbergi. *pryeri.* *agenor.* *primigenius.* *polymnestoroides.* *depelchini.* *rhetenorina.* *butlerianus.* *esperi.* *vinius.* *phoenix.* *alcanor.* *distantianus.*

hindwing large; Malacca to Hainan, China, and Formosa; these two tailed forms, which are connected by transitions, probably occur everywhere. From Formosa a further tailed form is known to me, which is strikingly like specimens of ♀-f. *agenor* with very light hindwing: ♀-f. **titania** *form. nov.*, forewing sepia-colour, with dark stripes; on the hindwing a very small cell-spot, a row of 7 discal patches, of which the 3.—7. are very large, and a row of large marginal spots white, the posterior marginal spots slightly yellowish, the black vein-stripes thin, beneath the cell-spot is wanting and the discal patches are abbreviated basally. — **anceus** *Cr.* is the race which inhabits Sumatra, Nias and Batu. In the ♂ the upper surface is very similar to that of the ♂ of *agenor*; beneath the cell-stripes and discal stripes of the forewing are broad and the distal-marginal area of the hindwing is blue-grey, often somewhat yellow at the anal angle, in exceptional cases the yellow tint is deeper and more extended. In this race also the ♀ does not occur everywhere in the same forms; the abdomen is posteriorly nearly always yellow; the hindwing in the dark forms is above more densely scaled with blue than in the other Malayan races, the basal spot of the forewing above is red or white, not yellow, the tailless forms with white band on the hindwing always bear beneath two rows of black spots and the tailed form is likewise easy to distinguish from the corresponding form from other districts, as described below. The principal types of the ♀ are: ♀-f. **erebinus** *Haase* (30 a), abdomen black or posteriorly yellow; forewing dark, between cell and apex more or less extended white, basal spot always red; hindwing above (as also the forewing) paler than in the ♂, but quite as densely scaled with blue; Sumatra. ♀-f. **trochila** *form. nov.*, forewing with red basal spot and often a distinct white patch between cell and apex; upper surface of the hindwing at least in the middle scaled with blue, distally pale, in addition to the black submarginal spots with a row of smaller discal spots; Sumatra, Nias, Batu. ♀-f. **anceus** *Cr.* resembles the preceding form, but the basal spot of the forewing is white; Sumatra, Nias. ♀-f. **sitolensis** *Fruhst.*, similar to *anceus*, but the upper surface of the hindwing distally more or less yellow, the apex of the cell also yellow; only known from Nias. ♀-f. **gerania** *form. nov.*, forewing with white area between cell and apex, the basal spot red; hindwing with broad yellowish white band, which at least beneath bears two rows of black spots, abdomen posteriorly yellow; Sumatra. ♀-f. **ityla** *form. nov.*, like the preceding, the band of the hindwing white-yellow, the black submarginal spots very large, the distal margin blackened, the abdomen black; Nias. ♀-f. **butis** *form. nov.*, tailed, the basal spot of the forewing red, the border of the hindwing broadly black, the margin itself and the veins less deep black, the last white discal patch distally orange-yellow, sometimes also the last but one; abdomen yellow, a dorsal line and the under surface black; Sumatra. ♀-f. **hellopia** *form. nov.*, like the preceding form, but all or almost all the white discal patches of the hindwing distally yellow; Nias, Batu. The tailed form is the rarest in all the localities; the tail is sometimes scarcely widened at the tip. — **memnon** *L.* (♂ = atrovenatus *Goeze*, arbates *Zinken*, memnoides *Fruhst.*) (33 a). ♂: the blue streaks of the upper surface in general shorter than in the ♂ of *anceus*, on the hindwing commonly not reaching the cell; beneath the cell-stripes of the forewing less distinct and the discal stripes less broad basally and commonly not touching the cell; the distal area of the hindwing beneath blue-grey as in *anceus*, usually somewhat yellow posteriorly. In a ♂ from Java (Sukabumi) the streaks of the upper surface are glossy blue and cover almost the whole hindwing, also beneath the stripes of the forewing and the central port of the hindwing are cyaneous blue: ♂-ab. **sericatus** *Fruhst.* The ♀ as in *anceus* extraordinarily variable; the abdomen either entirely black or the sides and back with the exception of a dorsal line yellow; the hindwing above rarely with distinct glossy blue scaling; the basal spot of the forewing red or yellow, never white; the forms with broad, white area on the hindwing have also beneath only one row of black patches. We treat the specimens from Borneo, Bunguran, Banka, Bawean, Java and Bali as belonging to one geographical race, but several of the ♀-forms are confined to one or other of the islands, so that we have here no more than in *anceus* and *agenor* a geographically uniform subspecies. ♀-f. **gyrtia** *form. nov.*, forewing above with red basal spot and white subapical area, otherwise very dark; hindwing almost pure black, distally with very slight yellowish scaling; Borneo, corresponds to ♀-f. *erebinus Haase* from Sumatra. ♀-f. **dobera** *form. nov.*, forewing with sharply defined, black basal area, which does not reach the base of the lower median, and red basal spot, otherwise broadly striped with white, these stripes broadest towards the base and distally shaded with blackish brown, so that the forewing recalls the ♀♀ of *pryeri* and *thunbergi*; hindwing black, distally somewhat paler; Borneo. ♀-f. **laomedon** *Cr.* (= memnoides *Fruhst.*) (30b), forewing more or less brownish sepia-colour, with black base and black interneural stripes, red basal spot and usually a whitish subapical area; hindwing distally sepia-colour to yellow-grey, with two rows of black spots; abdomen black; Bunguran, Borneo, Java, Banka; the commonest form. ♀-f. **hiera** *form. nov.* (30 b), forewing as in the preceding form, hindwing with broad white or yellowish band and a row of black submarginal spots, the black discal patches absent also beneath, abdomen black; Java, Banka. ♀-f. **imperiosa** *Fruhst.* (48 b). Forewing white before the distal margin from the subcostal fork to the hindmargin, this band-like area posteriorly widened; the yellowish white area of the hindwing reaches the cell, in the apex of which a small white spot is placed; the extreme tip of the abdomen yellow; only known from Banka, where this form appears to be common. ♀-f. **isarcha** *form. nov.*, forewing as in ♀-f. *laomedon* of lighter or darker sepia-colour, with sharply defined black basal area and red basal patch; hindwing for the most part white, distally with yellowish tinge and a row of black patches, basally the white area reaches to about the middle of the cell, sometimes almost to the base; abdomen black; Java to Bawean, on Banka represented by the preceding form, on Borneo by the following one. ♀-f. **venusia** *form. nov.* (48 b), abdomen yellow as in the tailed forms, a dorsal line and the underside black, forewing

titania. *erebinus.* *trochila.* *anceus.* *sitolensis.* *gerania.* *ityla.* *butis.* *hellopia.* *memnon.* *sericatus.* *gyrtia.* *dobera.* *laomedon.* *hiera.* *imperiosa.* *isarcha.* *venusia.*

as in the preceding, but the distal margin not darker than the disc, the hindwing nearly to the base yellowish white, the base and a row of large submarginal patches black, the distal margin less densely dusted with black than in the preceding form, the veins thinly black; only on Borneo. The tailed form known from Java and Banka,
achates. ♀-f. **achates** *Sulzer* (= achatiades *Esp.*) (33 a), is characterised by the yellow colour of the basal spot of the forewing and of the posterior marginal spots of the hindwing. This form, which is a copy of *P. coon*, is replaced
anura. on Borneo by a tailless one, ♀-f. **anura** *nom. nov.* (= javanus *Haase* nec *Felder*), in which the basal spot of the forewing is red and the discal spots of the hindwing are more or less strongly orange and often reduced; the abdomen as in ♀-f. *achates* yellow, with black dorsal line and underside, the dorsal line often widened. The occurrence of this tailless form, which is otherwise similar to the tailed ♀-f. *achates*, and the existence of the above described tailed form *titania* (p. 73), on Formosa, which otherwise resembles the tailless ♀-f. *agenor*, seem to indicate that originally all the ♀♀ of *P. memnon* were tailed, as is still the case in *P. lowi* and also in the monomorphic
oceani. ♀♀ of *P. mayo, ascalaphus* and *oenomaus*[1]). — **oceani** *Doh.* ♂: the stripes of the forewing above and beneath very strongly reduced; the blue stripes of the hindwing narrow and placed at a distance both from the cell and the margin; the red basal spots of the under surface on both wings suppressed except for a few scales. ♀ only known in one form; body black, forewing above with quite small, red basal spot, which is larger beneath, the red basal spots of the hindwing beneath very small; both wings above dark, the forewing gradually somewhat lighter distally, the hindwing with scattered blue scales in the distal half, somewhat paler distally than basally, on the under surface a broad grey marginal band, which encloses the black submarginal patches but not the discal
perlucidus. ones. Engano. — **perlucidus** *Fruhst.* ♂: the blue-grey stripes of the upper surface of both wings and of the underside of the forewing extend close to the distal margin; those of the hindwing above are remote from the cell and form a proximally almost uniformly concave broad band; the distal-marginal area of the hindwing beneath usually blue-grey, sometimes more or less extended orange; the length of the forewing in the Tring Museum specimens
nesocles. varies from 60—70 mm. The ♀ in two tailless forms: ♀-f. **nesocles** *form. nov.*, forewing dark sepia-brown, the black basal area not sharply defined, the light stripes pale brown, the basal spot red, beneath a row of feebly indicated light submarginal spots; hindwing brownish black, in the distal third paler, with distinct large black submarginal spots, beneath the distal third grey, posteriorly and anteriorly yellowish, besides the large submarginal spots with a row of small black discal spots, of which the anterior ones are united with the dark proximal
nysala. area of the wing. In the otherwise similar second form, ♀-f. **nysala** *form. nov.*, the hindwing has a white band
clathratus. consisting of large patches, which is usually somewhat yellowish. Lombok. — **clathratus** *Rothsch.* (27 b). ♂: as the preceding; but the stripes of the forewing are less distinct and shorter on both sides; length of the forewing 52—60 mm The ♀ with dirty yellowish white band on the hindwing; beneath without traces of submarginal spots on the forewing and with four very small black discal spots in the white patches of the hindwing. Sumbawa.
merapu. — **merapu** *Doh.* A large form, like many of the Sumba butterflies. Only the ♂ known: forewing strongly curved, 66—75 mm long, above almost entirely without stripes, beneath these are mostly more distinct, but are always placed 4—5 mm from the margin. Hindwing more elongate than in the other Malayan races, posteriorly narrower, the stripes of the upper surface narrow, remote from the cell and not reaching the margin; the large black submarginal spots of the under surface margined with ochre-yellow, the black discal patches entirely confluent
subclathratus. with the black part of the wing. Sumba, rare in collections; 4 ♂♂ in the Tring Museum. — **subclathratus** *Fruhst.* ♂: length of the forewing 50—66 mm, large specimens closely approximate to *merapu*; the stripes of the forewing feebly indicated, beneath as in *merapu* placed at a distance from the margin; the stripes of the hindwing beneath even weaker than in *merapu*, usually only the proximal ends (halfway between cell and distal margin) distinct; the black marginal spots on the underside of the hindwing in small specimens broadly edged with orange, in large examples this edging more grey, in all specimens the black discal spots united with the black area of the wing. ♀ tailless, corresponding in the markings to ♀-f. *achates*; forewing paler than in the ♀♀ of *clathratus* and *perlucidus*, hindwing with small cell-spot and a band of large, white, partly yellowish discal spots, which are separated by broad black vein-stripes, the marginal spots distinct. Flores, taken by A. Everett in November; the smallness of the specimens is probably explained by the long drought which prevailed in Flores when Everett visited the island (in 1896). The Tring Museum possesses several ♂♂ from Adonara and Pantar, likewise captured by Everett, which attain a considerable size (forewing 65—70 mm long), but otherwise agree well with large Flores specimens. The only ♀ from Pantar, with the forewing 80 mm long, has a larger cell-spot than the only ♀ known to me from Flores.

P. rumanzovia *Eschsch.* (♂ = krusensternia *Eschsch.*, floridor *Godt.*, amalthion *Bdv.*, ciris *Fruhst.*, spinturnix *Fruhst.*) (26 c). Tailless, but with distinct tooth at the 3. radial; both wings beneath with large, brilliant red basal patch; the submarginal and admarginal spots of the hindwing likewise glaring red. ♂ black, forewing with rather faint bluish grey stripes before the distal margin, of which the anterior ones mostly extend nearly to the cell; hindwing between the veins with broad bluish grey double stripes, which form a very broad band, the inner margin of which is twisted somewhat in S-shape. The anterior red spots of the hindwing beneath united into hooks and the posterior ones into rings. Some ♂♂ have above a red anal ring on the hindwing. In the ♀ the forewing in the cell and along the veins with white-grey stripes which are light, especially beneath;

[1]) Cf. Piepers, in Iris XVI, p. 247 (1903).

several forms: ♀-f. **semperinus** *Haase* (26 c), forewing almost as dark as in the ♂, but also above with large red basal spot, which is continued on the hindwing by a red band parallel with the abdominal margin; the rest of the hindwing above black with blue stripes; but the longitudinal band is often more or less whitish and widened and in that case a number of admarginal and submarginal spots are also present. The second main form is ♀-f. **rumanzovia** *Eschsch.* (= descombesi *Bdv.*) (27 a). The stripes of the forewing above and beneath at least partly white, the hindwing with large white central area, which extends from near the abdominal margin into the cell; according to SEMPER the specimens of this form from the Philippines have always a red basal spot on the upperside of the forewing; on Siao, Sangir and Talaut on the contrary the basal spot is often very small or entirely absent, some specimens moreover present a very strikingly different appearance through the white area of the hindwing being reduced and the 4.—6. admarginal spot very large, isolated[1]) and red-white: ♀-f. **eubalia** *form. nov.* (type from Siao) (48 c). — Larva green, with strongly swollen thorax; a spectacle-band on the thorax and behind it a raised yellowish band, which is connected laterally with a yellowish or greenish longitudinal stripe, on the abdomen an oblique band and a transverse one, not interrupted and like the anal segment whitish; the scent-fork orange. Pupa as in *P. memnon*. The butterfly on all the islands of the Philippines (Mindoro, Luzon, Mindanao, etc.), as well as on the Siao, Sangir and Talaut Islands to the north of Celebes; common. The *semperinus*-form of the ♀ resembles *P. semperi*, the red longitudinal stripe on the wings mimics the red abdomen of *semperi*; but this form is also found on the Talaut Islands, where *semperi* does not occur.

semperinus. *rumanzovia.* *eubalia.*

P. deiphobus. Very nearly allied to the preceding species. Forewing much less falcate. With or without tail, the patches of the under surface as brilliant red as in *rumanzovia*. ♂: upper surface of the hindwing before the distal margin with a broad band composed of light blue stripes, the inner margin of which is uniformly concave. ♀: forewing with thin white fringe-spots; the red admarginal spots of the hindwing, and especially the anterior ones, broadly confluent with the white fringe-spots. This quick-flying butterfly is especially common near the settlements, where Citrus trees grow in the gardens, rarer in the woods. The larva still undescribed, probably similar to that of *memnon*. The Moluccas and Waigeu, perhaps also in New Guinea. — **deiphontes** *Fldr.* (29 a). Tailless, but with distinctly projecting tooth at the 3. radial. ♂: the blue stripes on the upper surface of the hindwing densely scaled, more or less united in pairs and the patches thus formed distally emarginate. ♀: forewing from the base to the 2. median brownish black, then lighter, with brownish black streaks between the veins, on the under surface only the light streaks placed behind the 2. median basally white, the others all darkened. Hindwing always with white discal area and anteriorly near the apex with metallically blue scaling. ♂♂ and ♀♀ which have yellowish instead of red spots on the hindwing are ab. **flava** *Oberth.* Morty, Halmaheira, Ternate and Batjan. — **deipylus** *Fldr.* ♂ tailed, the band of the hindwing as in *deiphontes*, but the black interneural stripes on the whole even thinner. The ♀ likewise tailed, the forewing darker than in *deiphontes*, the posterior grey-brown stripes not whitish basally, the white cell-spot of the hindwing only indicated. Waigeu and perhaps also Dutch New Guinea. — **deiphobus** *L.* (♀ = alcandor *Cr.*) (28 a, b). Tailed. ♂: the grey-blue stripes on the upperside of the hindwing much further from the distal margin than in the preceding forms and mostly also much thinner. ♀: the part of the disc of the forewing placed below the cell and also the adjoining part of the cell itself much lighter; the markings of the hindwing individually variable. Specimens (♂♀) in which all the red is replaced by yellow are ab. **hypoxanthos** *Röb.* On Ceram, Saparoea, Amboina, Buru and Obi; common.

deiphontes. *flava.* *deipylus.* *deiphobus.* *hypoxanthos.*

P. protenor. ♂ and ♀ similar. ♂ black, wings with bluish gloss; hindwing long, without tail, from the apex of the costa towards the anal angle almost uniformly broad, with long white costal patch, which is covered by the forewing. Under surface paler, especially on the forewing, which is striped with whitish in the cell and on the disc; hindwing with red submarginal spots, of which the central ones are usually entirely absent, whilst the 7. and frequently also the 6. are united into rings with the marginal spots. ♀ much paler than the ♂. Larva green, a spectacle-band on the thorax, a black-edged band on the 4. segment, two oblique bands on the abdomen and the anal segment brown mixed with white; the prolegs grey; on Zanthophyllum. The butterfly common in most localities, often in swarms on moist sand at the banks of rivers, also visits flowers, being especially fond of thistles. During its slow and somewhat tumbling flight it moves the wings only slowly up and down, which gives it a somewhat clumsy appearance. The spring specimens are smaller. In the mountain-valleys of North India, in Burma, Tonkin, China, Hainan and Formosa. — **euprotenor** *Fruhst.* (= protenor *auct.*, euanthes *Fruhst.*, sulpitius *Fruhst.*). Upper surface of the hindwing usually sprinkled with blue scales to beyond the 3. radial. Distributed from North India to Burma, northwards beyond Tonkin to Hainan. — In **protenor** *Cr.*, from China and North-West India (see vol. I, pl. 3 b), the blue dusting of the hindwing above mostly does not reach the 2. radial, also the under surface of the forewing is on the whole less whitish than in *euprotenor*. Not sharply distinguished from *euprotenor*. — **amaura** *subsp. nov.* As in the Chinese form the blue dusting on the upperside of the hindwing is always very much reduced and usually almost entirely absent. Beneath the forewing is darker

euprotenor. *protenor.* *amaura.*

[1]) This ♀ strongly recalls the *deiphontes*-♀ from the Northern Moluccas, and was recorded by SEMPER as such.

than in the preceding forms, the pale discal stripes are only white distally and do not extend so near to the distal margin, hence the latter is more broadly black than in *euprotenor* and *protenor*. Formosa, common.

demetrius. **P. demetrius** *Cr.* Very nearly allied to the preceding species. Both sexes tailed (see vol. I, 3 c). The summer specimens as in the preceding species are larger than the examples of the spring brood (from hibernated pupae). Japan, Loo Choo Islands, East and Central China (teste LEECH), according to BUTLER also on Formosa. — *liukiuensis.* **liukiuensis** *Fruhst.* (= sitalkes *Fruhst.*) differs, though not quite constantly, from the priority form, which occurs in Japan, by broader wings and larger red submarginal spots on the hindwing; moreover the upper surface in the ♂ is deeper black and the blue scaling on the upperside of the hindwing of the ♂ is reduced. The number of the red spots on the upper surface of the hindwing is not constant either in *demetrius* or in *liukiuensis*; ♀♀ occur both in Japan and on Okinawa with a complete row of red spots. Okinawa and Ishigaki; Formosa?, China?

P. rhetenor. Body and wings bluish black, the abdomen laterally somewhat paler. The distal two-thirds of the forewing lighter, with black stripes between and on the veins, beneath in the ♂ more or less white-grey, above and beneath, in many ♂♂ only beneath, with red basal spot. Hindwing elongate, with strongly undulate distal margin; in the ♂ with projecting tooth at the 3. radial or without indication of a tail, above unicolorous, with scattered blue scales on the disc and red or white anal ring, before which is placed usually a second ring and sometimes a part of a third, beneath the base, as well as the abdominal margin of the hindwing is occupied by a broad dull red stripe, in which are placed black discal and submarginal patches, before the margin one or more dull red spots, of which the posterior ones are often united into rings with the red marginal spots, on the disc a dull black spot, which corresponds to the white patch of the ♀ (this spot was erroneously regarded by MOORE as secondary sexual character) and in Chinese specimens is often wanting. In the ♀ the hindwing has a broad rounded tail and a white discal area, also the red marginal and submarginal spots are larger than in the ♂. The earlier stages are not known. The ♀ is a mimic of the Aristolochia Papilios *P. dasarada* and *philoxenus* of the same localities. The butterfly occurs in North India all through the summer and ascends to about 6000 ft. — *rhetenor.* **rhetenor** *Westw.* (= turificator *Fruhst.*; ♀ = icarius *Westw.*; ♂ = alcmenor *Fldr.*, albolunata *Fruhst.*, publilius *leucocelis.* *Fruhst.*) (29 b). ♂: forewing often with large white patch at the hindmargin (♂-ab. **leucocelis** *ab. nov.*); the hindwing with distinct blue scaling on the disc and hardly projecting marginal tooth at the 3. radial, beneath with dull black discal spot before the 2. radial and without red submarginal spots from the 2. radial forwards. ♀: the white discal area of the hindwing consists of a cell-spot and 3 or 4 discal spots. Nepal to the Shan States and Tenas- *platenius.* serim. — **platenius** *Fruhst.*, known from West and Central China, doubtless also occurs in southern China. The hindwing in ♂ and ♀ is somewhat more sharply dentate than in the Indian form; in the ♂ the blue scaling on the upper surface of the hindwing is much reduced, whilst in the ♀ the white discal area is smaller.

thaiwanus. **P. thaiwanus** *Rothsch.* (= annaeus *Fruhst.*) (32 d ♀), which by a lapsus was described as a form of *protenor*, is much more strikingly different in the ♀ than in the ♂. ♂: under surface of the forewing almost entirely black, the grey stripes being reduced as in many butterflies from Formosa; the red area on the underside of the hindwing is much more extended than in the other forms and there are large red submarginal spots as far as the subcostal. The ♀ tailless; forewing paler than in the ♀ of *P. rhetenor*; hindwing from the subcostal to the anal margin with a macular band, the anterior patches of which are large and white and the posterior ones smaller and reddish, the posterior submarginal spots united into rings with the marginal spots; under surface as in the ♂ with larger markings than in *P. rhetenor*. — Formosa.

Bootes-Group.

Head and a lateral stripe on the abdomen red; base of the wings beneath red. Sexes similar, tailed, both mimics of Aristolochia Papilios.

P. janaka. Sexes similar, with spatulate tail; head, a part of the thorax and a lateral stripe on the abdomen dull red; forewing black, above more weakly, and beneath more strongly grey, with usually deep black stripes; hindwing with white discal area, which is wanting in the Chinese form—only 1 ♂ known —, is larger in the ♀ than in the ♂ and never enters the cell, in addition to the anal spot 1—4 submarginal lunules present. Beneath a red band covers the base of both wings and extends along the abdominal margin of the hindwing. The larva and pupa not known. The butterfly in the spring in North-West India, Sikkim and West China; such a faithful copy of the Aristolochia Papilio *P. latreillei* that MOORE was misled into uniting *janaka* and the following *janaka.* species *bootes* with *latreillei, adamsoni, nevilli*, etc., in one of his „genera"! — **janaka** *Moore* (= sikkimensis *Wood-Mas.*) flies in Sikkim at from 3—5000 ft. in May and June, as well as in the North-Western Himalayas ♂ and ♀ with white discal patches on the hindwing and a pale red double spot at the tip of the tail. — *dealbatus Rothsch.* (see vol. I, 3 a), from West China, has no discal patches and no spots in the tail.

P. bootes. Very similar to the preceding species, principally distinguished by the red basal area of the under surface not being continued at the abdominal margin of the hindwing. Assam and West China. — **bootes** *Westw.* (27 b), from Assam, has always a reddish white double spot at the tip of the tail. — In *nigricans Rothsch.* (= echo *Ehrm.*) (see vol. I, 3 a), from West China, the tail is black. Examples from Tse-kou are ab. *rubicundus Fruhst.*; do they really differ from the very variable *nigricans*? *bootes.*

3. Gloss-Papilios.

The upperside of the body and wings with green or blue metallically glossy scaling; in some forms this dusting is almost uniformly distributed over the whole upper surface, but most species have a large metallic patch or a band, and in others the greater part of the upper surface is glossy blue or green. The under surface is always dark (protectively coloured). In the larvae, so far as known, the thoracic segments are thickened, scutellated.

Paris-Group.

The upper surface of the wings dusted with green, forewing with or without thin green or yellowish band; hindwing without metallic patch or anteriorly with thicker metallic scaling or with metallic patch, which is sometimes prolonged into a posteriorly thin band. The submarginal spots of the hindwing beneath red or yellow, ornamented with a curved blue mark.

P. elephenor *Dbl.* (34 a). Head pale ochre-yellow, the sides of the abdomen yellow-grey; ♂ and ♀ tailless. ♂: forewing with hair-streaks, and like the hindwing sprinkled over with green-blue scales; hindwing narrower than in *protenor*, with red anal eye-spot and sometimes a red submarginal lunule between the two median veins. Under surface of the forewing blackish grey, with black stripes on and between the veins; forewing black, with a row of red submarginal lunules. ♀ quite similar to the ♂. — Assam: Khasia and Naga Hills, Cachar, Sadiya, Jorehat. Rare, especially the ♀. *elephenor.*

P. dialis. Body black as in the following species, above dusted with metallic scales. Upper surface of the wings dusted with green, hindwing with blue tinge in the costal region, but without metallic patch, at the anal angle a red ring; the tail is absent, or is stunted, or as long and broad as in *P. bianor*, with all the intermediate stages. The under surface similar to that of *bianor*, but the forewing always less extended dark than in the respective form of *bianor* from the same country. The scent-streaks of the ♂ always narrow and widely separated, of much more uniform width than in *P. polyctor*, in which the stripes are likewise separated. The ♀ is less densely metallically scaled than the ♂ and has on the upperside of the hindwing a red submarginal spot behind the 2. median. The earlier stages are unknown. The butterfly is rare in collections. Fruhstorfer is the only collector who captured even a small series. He found the insect near the native habitations on refuse-heaps before and among the huts, as well as on the moist sand of a river-bank. Though the butterfly is very shy, yet when driven away it frequently returned again to the same place. When feeding it always keeps the wings closed. During its circling, hovering flight it presents a fine spectacle by its graceful movements (Fruhstorfer). Distributed from the Shan States to Central China and Formosa. The genitalia of most species of this group are so similar that scarcely any distinct differences can be shown. — **schanus** *subsp. nov.* ♂: upper surface of the hindwing somewhat less blue than in the next subspecies, with 1—3 red submarginal spots besides the anal eye-spot, and very short stumpy tail, which projects less than in the other forms. Beneath the forewing only blackish to the base of the lower median and the submarginal spots of the hindwing more yellowish. The scent-stripes very narrow, no stripe on the submedian fold. Southern Shan States: 1 ♂ in the Tring Museum, a second in the Museum at Calcutta (coll. De Nicéville). — **doddsi** *Janet* (= megei *Oberth.*) (34 a). Tail either quite short or long, broad and spatulate, with all the intermediate stages. ♂ only with red anal eye-spot on the upperside of the hindwing, ♀ in addition with red submarginal spot. The black basal area on the underside of the forewing reaches in the ♂ to the base of the upper median, and in the ♀, which I only know from the description, probably does not extend quite so far. Tonkin. — **cataleucas** *Rothsch.* (= cataleuca *Fruhst.*). A small form, of which only a few ♂♂ are known, which were taken by the late J. Whitehead in the Five-Finger Mountains of Hainan. Forewing with 2 very thin distinct pilose stripes and one indistinct one; the black basal area of the under surface is very strongly reduced and remains at a distance from the lower median. The tail short and narrow or longer and spatulate. Hindwing above with 3 red submarginal spots. — **dialis** *Leech.* Tailed; the black basal area of the forewing beneath reaches to the lower median, the scattered light scales on the under surface of the hindwing are almost all green, upper surface with 2 red submarginal spots. West China, ♂ in coll. Leech; a second, slightly different ♂ from Kiatim, North-West Fokien, in the Tring Museum. — **andronicus** *schanus.* *doddsi.* *cataleueas.* *dialis.* *andronicus.*

Fruhst. (not *Ward*). Only known to me from the description. The darkest of the known *dialis*-races. The tails long and spatulate; the upper surface of the hindwing without red spots except for the anal ring, otherwise confusingly similar to that of *bianor formosanus*; without the glossy green ornamental patch of the hindwing (which, however, is often absent in *formosanus*, also many *formosanus* have above small red submarginal spots); forewing with narrower sexual stripes. Nothing is said as to the colouring of the forewing beneath. Formosa.

P. bianor. Geographically as well as seasonally very variable. ♂: the pilose stripes broad, the posterior three usually united, when they are separated the stripe of the lower median remains broader than the interspace, which separates it from the stripe of the submedian fold; upper surface of the forewing dusted with green or green-blue, this scaling commonly condensed into a band before the narrowly dark distal margin; upper surface of the hindwing anteriorly blue or blue-green and posteriorly dusted with green, commonly with a more thickly scaled large green or blue patch (or a similar band), a red anal spot, besides 0—4 red submarginal spots and at least anteriorly some distinct green submarginal spots. The black basal area of the forewing beneath always extends beyond the base of the upper median, sometimes the whole wing is black; under surface of the hindwing with a complete row of red submarginal spots. The ♀ with less dense metallic scaling; the red spots on the upperside of the hindwing usually more numerous and larger than in the ♂. The butterfly occurs from North Japan to Tonkin and West China and appears to be fairly common in all its localities, sometimes occurring in profusion. Like the allied species the ♂♂ congregate on moist sand and visit flowers. The larva is green with 2—3 light oblique bands, on Aurantiaceae. Although the butterfly is frequently bred in the northern parts of its range, no sufficient description of all the earlier stages has yet been published. — The Palaearctic forms of *P. bianor* have

okinawensis. been dealt with in vol. I, p. 10. — **okinawensis** *Fruhst.* Only the summer form known, which is relatively small. Very similar to *dehaani* of Japan, smaller than the summer form of this, darker on both surfaces; the upper surface of the hindwing distally broadly black, as in *dehaani*, the blue costal area is placed at a distance from the submarginal spots and surrounds the apex of the cell; the submarginal spots of the upper surface usually conspicuously blue, those of the under surface somewhat larger than in *dehaani*. In the ♀ the submarginal spots of the hindwing beneath especially large and sometimes connected with the likewise enlarged marginal spots.

junia. The grey discal area of the forewing beneath is similar to that of *dehaani*. Okinawa. — **junia** *subsp. nov.* Herr FRUHSTORFER refers the specimens from Ishigaki-sima to *okinawensis*. Two ♂♂ of the summer brood received from him, however, agree much better with the forms from Formosa and China. Shape of the wings much as in *formo-*

sanus; the blue costal area of the hindwing reaches the middle of the cell and extends distad to the submarginal spots, so that at the proximal side of these spots instead of the broad black band of *okinawensis* and *dehaani* there are only black patches. Beneath *junia* resembles the Chinese *bianor* in that the forewing is grey from the apex of the cell nearly to the distal margin and the narrow black distal margin is only a little widened at the apex;

formosanus. the marginal spots of the hindwing are larger than in *bianor* and *formosanus*. — **formosanus** *Reb.* is the form from Formosa; it is very similar to *bianor*, but is distinguished from it nearly always by a considerable reduction of the grey stripes of the forewing beneath, also the red submarginal spots of the hindwing are smaller and are absent

bianor. above in most ♂♂ (except for the anal spot). Common. — **bianor** *Cr.* (vol. I, 4 c). The costal area of the hindwing above usually blue to the middle of the cell and distally to the submarginal spots, more rarely grey, in small

majalis. spring specimens (f. **majalis** *Seitz*, see vol. I, p. 10. vol. I, 3 c) sometimes with more densely scaled large metallic patch, in addition to the anal spot there are mostly 3 or 4 red submarginal spots, in the ♀ sometimes 6, in the large summer specimens the green scaling of the posterior part of the wing is often separated from the submarginal spots by a broad black area. Beneath the grey discal area of the forewing is always broad, it also extends nearly to the distal margin and in most specimens goes far into the cell. East, Central and West China; in the mountains of West China the butterfly ascends to 6000 ft. and between 5 and 6000 ft. occurs together with the nearly allied species *P. syfanius Oberth.* (vol. I, pl. 5 b). — No *bianor*-form is yet known from Hainan, on the other hand FRUHSTORFER captured a considerable series in Tonkin, among which examples with unicolorous blue costal area on the upper surface of the hindwing predominate. Such specimens agree well with South Chinese ones. But there were also many specimens in which the blue scaling of this area is condensed near the submarginal spots into a large bipartite patch and the 1. submarginal spot is enlarged. Similar specimens also occur in China, but rarely; the name originally applied to all the specimens from Tonkin may be retained for such examples,

gladiator. as ab.. **gladiator** *Fruhst.*

P. polyctor. Very nearly allied to *P. bianor*; but as both butterflies occur together in Tonkin without intergrading, they must be recognised as separate species. The pilose stripes of the ♂ are always separated, even the stripe on the submedian fold is isolated, those placed on the two median veins are more strongly narrowed at both ends than in *P. bianor* and consequently more spindle-shaped; the green scaling on the upperside of the forewing is usually condensed into an anteriorly abbreviated narrow discal band. The hindwing in ♂ and ♀ with large blue or blue-green patch, which reaches from the costa at least to the 2. radial vein, is commonly prolonged into a band, and with which the upper submarginal spots are confluent; besides the anal spot there are 3 or 4 red submarginal spots. The grey distal area of the forewing beneath always enters the cell. The ♀ is

larger and especially on the forewing paler than the ♂. The several earlier stages described in detail in Moore, Lep. Ind. vol. VI, p. 53—56. The young larva bears spines which disappear in the later stages, and is very dark. In the half-grown and full-grown larvae, which are green, the thorax is thickened above like a shield; the margin of the shield and also four oblique stripes on the abdomen are yellowish green, a longitudinal line above the prolegs is white. On Zanthoxylum alatum. The pupa bluish green, usually with brown markings, the lateral keel very distinct, brown or white, the horns on the head about as long as they are broad at the base, the thoracic horn broad, low, pointed. The butterfly is in most localities very common, with the exception of the eastern districts, where hitherto only a few specimens have been captured. Kashmir to Tonkin and Siam. — **triumphator** *Fruhst.* The blue patch on the upper surface of the hindwing small, the 2. submarginal spot only partially confluent with it. Tonkin; Chentaboon (somewhat aberrant). — **significans** *Fruhst.*, from Tenasserim and Lower Burma, has on the upperside of the forewing a small, round, white spot before the hindangle. — **ganesa** *Dbl.* (34 b). Forewing usually with green discal band, which in specimens from Assam is often only very weakly indicated, but sometimes is broader than in many Sikkim examples. Hindwing with blue patch, which reaches to the 3. radial and is more or less strongly produced distad behind the subcostal and 1. radial. In two of the ♂♂ in the Tring Museum (both from the Khasia Hills) the submarginal spots on the upperside of the hindwing are larger than the normal and beneath extraordinarily enlarged: ab. **porphyria** *ab. nov.* (48 a). The aberration corresponds to *P. paris gedeensis* ab. *prillwitzi* from Java. — **polyctor** *Bdv.* (vol. I, 5 b) has in ♂ and ♀ on the upperside of the forewing a golden green band, which is distinct to the subcostal fork, the metallic patch of the hindwing is usually more green and commonly prolonged into a band; the grey stripes of the forewing beneath are strongly reduced and sometimes almost entirely absent, whilst the yellowish grey dusting on the under surface of the hindwing is more extended than in *ganesa*. The summer form, f. aest. **polyctor** *Bdv.*, is not quite so large as *ganesa*, whilst the spring form, f. vern. **peeroza** *Moore*, is much smaller. The butterfly is very common in the valleys of the North-Western Himalayas up to 6000 ft. and extends in Kashmir into the Palaearctic Region. The ♂♂ commonly rest in large numbers on the moist sand of river-banks.

triumphator. *significans.* *ganesa.* *porphyria.* *polyctor.* *peeroza.*

P. paris. Upper surface of the body and wings dusted with green, forewing with or without narrow green band, hindwing with large patch, which is green or blue according to the fall of the light and is always broadest behind the 1. radial, usually the patch is connected with the abdominal margin by a narrow green band, at the anal angle a red ring. Under surface brown-black, sprinkled with yellowish grey scales; forewing with grey discal stripes, which especially towards the hindmargin are light and towards the costa are longer and more indistinct; hindwing with a complete row of red or yellowish red submarginal lunules, on or at which are placed purple-blue curved marks, the posterior submarginal spots often united into rings with the marginal spots. ♂ usually without, sometimes with thin scent-stripes. The earlier stages of this butterfly are only known of *arjuna* (see below). The insect is very common at lower elevations in wooded districts; the ♂♂ are fond of visiting flowers and often rest in crowds on moist sand; their flight is very swift, and like many butterflies they have a habit of returning again and again in the same course. — **hermosanus** *Rebel* (= neoparis *Fruhst.*). A small form from Formosa. On the forewing the green band is absent or only feebly developed and beneath the grey band in the ♂ mostly only indicated and also in the ♀ less pure grey than in continental specimens. The metallic patch of the hindwing is small, especially in the ♀, and the submarginal spots on the under surface are mostly more yellowish. The ♂ has usually a distinct pilose stripe on the 2 median, a weaker one on the submedian, and sometimes a third on the 1. median; but these stripes may also all be absent. The presence of this scent-organ misled Rebel into referring the form to *P. polyctor*. According to Fruhstorfer there occurs on Formosa together with „*polyctor hermosanus*" also a *paris*-form, which, however, according to his description, is nothing but *hermosanus*. But it appears to me doubtful whether the specimen briefly described by Fruhstorfer as ♀ of *hermosanus* belongs here. — **tissaphernes** *Fruhst.* Likewise a small form; forewing more obtuse than in *P. p. paris*, the green band only feebly or not at all developed, the under surface as dark as in *hermosanus*, above the metallic patch of the hindwing larger. Hainan; a series of both sexes in the Tring Museum. — **chinensis** *Rothsch.* (vol. I, 5 b) is the form from Central and West China, in which the metallic patch is reduced from behind; the smaller spring specimens are f. vern. **gemmifera** *Fruhst.* — **paris** *L.* (= majestatis *Fruhst.*, decorosa *Fruhst.*) (34 c). As in *tissaphernes* the forewing of the ♂ has in exceptional cases a distinct pilose stripe on the 2. median, slight indications of this stripe are of common occurrence. The metallic patch is as large as in Hainan specimens, but the grey band on the underside of the forewing mostly of purer colour. The larger summer form is f. aest. **paris** *L.*, and the smaller spring form (dry season) f. vern. **splendorifer** *Fruhst.* Some of the examples from South-East China are not distinguishable from Indian specimens, while others bear a close resemblance to *tissaphernes* and *hermosanus*. Distributed from Hong-Kong to Malacca and North-West India. — **tamilana** *Moore* (34 c). A large form, with very large metallic spot on the hindwing and reduced grey band on the under surface of the forewing. In the South Indian hills. Bell saw a ♀ lay its eggs on Evodia roxburghiana. — **battacorum** *Rothsch.* With shorter wings than any of the preceding forms; forewing above entirely without green band or the latter is slightly indicated, beneath with narrow grey band, hindwing with large metallic area, which is almost as broad at the subcostal as at the 1. radial. The yellowish scaling of the hindwing beneath extends at the posterior veins to between the submarginal spots; the latter yellow-red, rather small, with very thin pale purple arcs. North-East Sumatra,

hermosanus. *tissaphernes.* *chinensis.* *gemmifera.* *paris.* *splendorifer.* *tamilana.* *battacorum.*

gedeensis. in the mountains; the flight extremely swift, low. — **gedeensis** *Fruhst.* Forewing without green band; the metallic area of the hindwing narrower than in *battacorum*, behind the lower median on the other hand broader, hence on the whole more band-like; the submarginal spots on the underside of the hindwing more yellow and like the purple arcs larger; these purple arcs, as in *battacorum*, cover the inner margin of the submarginal *prillwitzi.* spots. In West Java, especially common on Mt. Gedé. ab. **prillwitzi** *Fruhst.* has been described from a ♂ with very strongly enlarged submarginal spots on the underside of the hindwing (cf. the similarly *arjuna.* developed aberration of *P. polyctor*). — **arjuna** *Horsf.* (35 a). As the preceding, but the forewing with *tenggerensis.* narrow green band. Central Java. — **tenggerensis** *Fruhst.* As the preceding, the band of the forewing, however, somewhat broader. East Java.

P. karna. Larger than the Malayan forms of the preceding species. The forewing, so far as is known, at most with a slight indication of a green band before the hindmargin; the metallic area of the hindwing nearly always separated from the cell, posteriorly broader than in the *paris*-forms and hence even more band-like than in *P. paris gedeensis*, the red anal ring very large, the grey scaling before the distal margin condensed into more distinct submarginal patches than in *P. paris*. The submarginal spots on the under surface of the hindwing reddish yellow, the 3 central ones reduced, the purple arcs large, the yellowish grey dusting of both wings less extended. In the ♀ the upper surface of the hindwing bears a yellow submarginal spot behind the costal vein. The earlier stages not known. The butterfly on Java, Sumatra and Borneo; much rarer than the *paris*-forms. This species *karna.* stands in the same relationship to *P. paris* as *P. iswara* to *P. helenus*. — **karna** *Fldr.* (35 b) is the smallest of the *discordia.* three known geographical forms; it flies in West Java, in the same districts as *P. paris gedeensis*. — **discordia** *Nicév.* (= discoidea *Nicév.*) is larger than *karna* and the central reddish yellow submarginal spots on the *carnatus.* underside of the hindwing are smaller. North-East Sumatra, in the Gajo highlands. — **carnatus** *Rothsch.* (= karnata *Fruhst.*) (35 a), from North Borneo, appears to be much less rare than the preceding forms and occurs also in the plains. Mostly as large as *discordia*, but many specimens not larger than *karna*; the inner margin of the metallic area between the subcostal and the 1. radial very oblique, the yellowish green submarginal spots very large, the reddish yellow submarginal spots on the underside of the hindwing reduced, the 5. nearly always absent.

P. arcturus. Sexes similar; the ♀ somewhat paler and larger, with larger red spot on the hindwing. The upper surface dusted with green, forewing with green, costally obsolescent submarginal band; hindwing darker than forewing, bearing in and before the apex of the cell a large blue patch, which behind the subcostal is produced to the distal margin, and a row of 3—6 red submarginal spots, as well as a red anal ring, the red spot placed behind the tail is rarely indicated; when the red spots are absent a green spot appears in their place. Beneath the forewing is grey in the distal half and posteriorly before the distal margin broadly grey-white; the hindwing has a complete row of red submarginal spots, some of which are often united into rings with the marginal spots. The ♂ without scent-stripes. The earlier stages are not known. The butterfly on paths and *arcturus.* openings in the woods. North-West India to Tenasserim, West and Central China. — **arcturus** *Westw.* (vol. I, pl. 5 c) occurs from Tenasserim to Nepal. The red submarginal spots on the under surface of the hindwing are large, the disc of the forewing beneath is posteriorly almost pure white and this band at the lower median broader than its distance from the cell; the short green band which is placed at the proximal side of the *arius.* anal eye-spot on the upperside of the hindwing is not thicker than the ring. — **arius** *Rothsch.* ♂: the blue spot of the hindwing extends somewhat further basad than in *arcturus*, the short green band at the anal eye-spot of the hindwing is broader, the red submarginal spots are smaller above and beneath, and the grey distal area on the underside of the forewing is less extended and not so pale. Kashmir and North-West India. — *arcturulus Fruhst.* is the form from West and Central China; the butterfly is apparently not yet known from tropical China.

hoppo. **P. hoppo** *Mats.* (48 c, 49 a). A magnificent species, similar to *arcturus*, in which the blue costal area of the hindwing is very large and the under surface of the hindwing has *two* rows of red lunules. — Formosa.

P. krishna. The upper surface dusted with green; forewing elongate, above and beneath with sharp yellowish discal band; hindwing anteriorly with broad blue spot, which is connected with the abdominal margin by a narrow green band, 4 submarginal spots and the large anal eye-spot purple-red, placed at a distan e from the distal margin; beneath the hindwing has a discal band composed of yellowish spots and a complete row of purple-red submarginal spots, the marginal spots reddish. The ♀ very similar to the ♂, larger, with broader *krishna.* wings. The ♂ without scent-stripes. North India and West China. — **krishna** *Moore* (34 a, b). Upper surface of the wings rather densely dusted with green, the band of the forewing above very sharply developed. Sikkim, Bhotan; perhaps also Assam. The butterfly from 3—9000 ft., it commonly flies according to ELWES on bare places on mountains the slopes of which are covered with forests consisting of chestnuts, oaks and magnolias. —

charlesi (!) *Fruhst.*, from Sze-chuan (West China), differs according to the author in the almost black upper surface of the wings, the partly obsolete band of the forewing and the more red submarginal spots of the hindwing. *charlesi.*

Palinurus-Group.

Upper surface with green or blue band on both wings; the submarginal spots of the hindwing beneath usually distinctly tri-coloured (blue-yellow-black).

P. crino *F.* (36 b). Upper surface almost uniformly dusted with green, the green or bluish band on both wings outside the cell; the tail with metallic spot at the tip. Under surface dark sepia-colour; forewing with a proximally almost uniformly concave grey band distally to the subcostal fork, this band anteriorly broad, posteriorly narrow, very variable; hindwing with pale yellow submarginal transverse spots, at the proximal side of which are placed similar grey- or blue-white spots and further towards the disc a row of yellowish grey, often diffuse spots, at the anal angle above and beneath a reddish ring or half ring. The ♂ usually with thin pilose stripes, which are absent in ♂-ab. **montanus** *Fldr.* (36 b, c). — Larva bluish green, the 1. and last segment with two short processes. Pupa green, angles of the head weakly projecting. On Chloroxylon. The butterfly is rather common in the plains, especially in the spring on Ceylon, but also occurs in the mountains up to about 6000 ft. The flight is very swift. Ceylon, South India, Calcutta. In the northern districts as well as in the higher mountains probably only an occasional migrant. *crino.* *montanus.*

P. buddha *Westw.* (35 b). The band of the upper surface broad, placed anteriorly on the forewing almost entirely in the cell and on the hindwing also entering far into the cell; the basal area of both wings dusted with green, on the other hand the distal-marginal area almost pure black; hindwing with yellow submarginal spot at the costal margin and anal angle, and in the ♀ in addition a second spot placed behind the subcostal; tail black. Under surface with very broad, proximally almost straight, grey band distally to the cell; distal margin of the hindwing pale, a row of narrow yellow submarginal spots, which are distally bordered with black and proximally with bluish white. ♂ entirely without pilose stripes. — Larva green, from the 5. segment onward with white longitudinal stripe above the legs, posteriorly on the thorax a white transverse line, which laterally is continued forwards and forms the boundary of the somewhat shield-shaped, swollen upperside of the thoracic segments; anteriorly and posteriorly a pair of short processes. Pupa almost uniformly curved, without thoracic horn, head produced in two long protuberances; underside from the lateral keel pale green, upperside dark green. Food-plant: Xanthoxylum rhetsa. The butterfly all the year round with the exception of June and July, commonest in September and October; it flies very quickly and high, seldom stops at flowers and is consequently difficult to catch. In the hills of South India, both in the woods and in open cultivated land. *buddha.*

P. palinurus. Similar to *P. buddha*, the band of both wings narrower, the distal-marginal area of the forewing dusted with green, the hindwing with large green submarginal spots; the grey band of the forewing beneath is placed very close to the cell and is basally concave. The earlier stages are not known. The butterfly according to MARTIN flies in wooded country and is very shy and agile; it occasionally comes into gardens and is fond of feeding at the flowers of Ixora, Lantana, etc., it is also often found at damp places on the forest-paths. HAUXWELL mentions that it has a habit of flying close over the water like a swallow, dipping its body in and then hurrying away. Burma to Sumatra and Nias, northwards to the Philippines. — **palinurus** *F.* (= regulus *Stoll*, brama *Guér.*, tubero *Fruhst.*, nikagoras *Fruhst.*) (35 b, c). The band of the forewing is very obliquely placed, being posteriorly at most 5 mm from the end of the submedian; both it and the band of the hindwing vary in width in all localities. In most of the specimens from North Borneo the band is slightly blue: ab. **solinus** *Fruhst.* The under surface varies especially in the size of the submarginal spots of the hindwing. Burma, Tenasserim, Malacca, Sumatra, Borneo. — **adventus** *Fruhst.*, from Nias, differs in both sexes principally in the larger submarginal spots of the hindwing beneath. — **angustatus** *Stgr.* Upper surface of the hindwing in ♂ and ♀ more broadly black between the discal band and the submarginal spots than in *palinurus* and *adventus*; beneath the pale band of the forewing is less curved and the pale marginal area of the hindwing broader than in these forms. Palawan. — **daedalus** *Fldr.* (35 c). The largest form. The green discal band of the upper surface broader than in the preceding subspecies, that of the forewing less oblique; otherwise similar to *angustatus*. Philippines, probably on all the islands, according to SEMPER almost all the year round, principally in May and October. — **nymphodorus** *Fruhst.*, from Bazilan, is said to be distinguished by a broad discal band on both wings and very large green submarginal patches on the hindwing. I have before me only an abnormal specimen, from which I can form no opinion as to the constancy of the characters given. *palinurus.* *solinus.* *adventus.* *angustatus.* *daedalus.* *nymphodorus.*

P. blumei. One of the most beautiful Papilios. Larger than *P. palinurus daedalus*, the upper surface similarly marked, but the band green-blue and the tail with the exception of the vein and the margins likewise blue. The yellowish grey distal band of the forewing beneath very broad, proximally straight or slightly curved; the yellow submarginal spots of the hindwing all very large, proximally margined with blue. Many ♂♂ have one or several very narrow pilose stripes on the upperside of the forewing. The ground-colour of the ♀ is paler

than in the ♂ and usually the blue band is narrower. Only known from Celebes; rare in the south of the island,
blumei. commoner in the north. — **blumei** *Bdv.* (36 a) is the northerly form. In the ♂ the band of the forewing entirely or almost entirely fills up the apex of the cell and in the ♀ the part of the apex of the cell which is not blue
fruhstorferi. is much narrower than the band. — In **fruhstorferi** *Röb.*, from South Celebes, the band of the forewing is placed at some distance from the apex of the cell, so that basally to the lower radial its distal margin enters the cell and the black apical part of the cell is at least half as broad as the band; moreover in both sexes the light distal area of the forewing beneath is broader and the basal area of both wings more thickly dusted with yellowish. In the Tring Museum 1 ♂ and 1 ♀ taken by W. Doherty and 1 ♂ (type) by H. Fruhstorfer.

Peranthus-Group.

The upper surface of the wings from the base to one or two thirds glossy green or blue, with the exception of *P. neumoegeni*, which bears a metallic band; the tricoloured submarginal spots of the hindwing beneath yellow-black-blue.

neumoegeni. **P. neumoegeni** *Honr.* (= maremba *Doh.*) (36 c). ♂: upper surface with the exception of the distal margin scaled with green; forewing with lighter green, densely scaled discal band, which is interrupted by a very large pilose patch, the green scaling sparse distally to the anterior part of the green band which is placed at the apex of the cell; hindwing with broad, light green discal band and submarginal spots of the same colour. ♀ recalling *P. palinurus*; not quite so densely scaled with green as in the ♂: forewing with green oblique band and feebly marked submarginal spots; the discal band of the hindwing narrower and anteriorly shorter than in the ♂. — Sumba, especially in the interior of the island.

P. peranthus. About a third or the half of both wings bluish green, this metallic area never reaching beyond the apex of the cell of the forewing, before the distal margin of the forewing a green band, which is very broad anteriorly and strongly narrowed posteriorly. The pilose stripes of the ♂ mostly confluent, never all completely separated, as at least the stripe placed on the submedian fold is united with the lower median. The ♀ paler than the ♂, especially in the distal part of the under surface, the metallic area mostly somewhat darker blue. The
peranthus. earlier stages are not known. In habits the butterfly resembles *P. palinurus*. — **peranthus** *F.* (37 a). ♂: the green submarginal band of the forewing anteriorly as broad as the black discal band or broader; the green basal area reaches to or nearly to the anterior angle of the cell. In the ♀ the green scaling of the submarginal area of the forewing above is very sparse. The inner margin of the pale submarginal area of the forewing beneath is mostly
transiens. placed basally to the subcostal fork. Java. — **transiens** *Fruhst.* (= kinesias *Fruhst.*, fannius *Fruhst.*, phoebus *Fruhst.*). The green area somewhat less extended than in *peranthus*, hence the black discal band of the forewing broader; as in Javan specimens the green submarginal band of the ♂ reaches only to the 1. median, rarely a green submarginal spot is indicated below this vein. The light distal band of the forewing beneath is placed distally to the fork of the subcostal. Bali to Alor; specimens are before me from Bali, Lombok, Sumbawa, Flores, Larentula,
intermedius. Adonara, Pantar, Alor. — **intermedius** *Snell.* (= fulgens *Röb.*). The basal area somewhat more densely scaled and bluer than in *transiens* and *peranthus*; the submarginal band of the forewing in the ♀ distinctly green to the submedian and in the ♂ continued to the 2. median or even to the submedian; anteriorly this band is usually
baweana. broader than in *transiens*. Bonerate, Djampea and Kalao. — **baweana** *Hag.* I have before me only the two ♀♀ described by Hagen; in these the blue-green basal area only reaches to the anterior angle of the cell of the forewing; the green submarginal band is much narrower anteriorly than the black discal band and its green scaling does not extend below the lower median; the costal and anal spots of the hindwing beneath are large and pale yellow, and, in the only well preserved specimen, appear also on the upper surface; the very light inner margin of the pale distal area of the forewing beneath is placed outside the furcation of the subcostal and before the middle
insulicola. is still more distinctly curved basad than in ♀♀ from Java. Bawean. — **insulicola** *Rothsch.* (37 b), from Saleyer, connects the preceding forms with *adamantius*, but most nearly approaches the latter. The costal margin of the forewing more curved and the distal margin more strongly emarginate than in the preceding forms. In the ♂ the green-blue basal area reaches on the forewing not quite to the upper median and on the hindwing to the apex of the cell and in the ♀ it is even somewhat more reduced, the pilose stripes broadly confluent, the green submarginal band narrower than the black discal band; the upper surface of the hindwing almost entirely without green submarginal spots, especially in the ♂. The grey discal band on the underside of the forewing is approximated to the cell, its inner margin crosses the stalk of the subcostal fork about halfway between fork and cell. In the
adamantius. Tring Museum 1 ♂ collected by A. Everett and 1 ♂ and 1 ♀ by H. Kühn, appears to be rare. — **adamantius** *Fldr.* (= macedon *Wall.*). A large form with long, falcate forewing and long, broad-tailed hindwing. The greenish blue basal area reaches on the forewing about to the lower median and does not quite fill up the cell of the hindwing, the green submarginal band is very broad and in many examples from North Celebes broader than in most of the specimens from the south of the island; the grey discal band of the forewing beneath is broad and extends nearly to the cell. The pilose stripe on the 1. median is mostly isolated and in many specimens the stripe on the submedian is absent. The ♀ very similar to the ♂, the basal area somewhat less densely scaled and the under

surface paler. From North, Central and South Celebes; common, especially in the hills. From the Sulla Islands no Gloss-Papilio is yet known.

P. lorquinianus. Very nearly allied to *P. peranthus*. ♂: the metallic area of the forewing much less straight distally than in *P. peranthus*, posteriorly broader, extending between the pilose stripes, forewing with blue or green submarginal band, hindwing from the subcostal with distinct submarginal spots of the same colour, the basal area of the hindwing always extends beyond the apex of the cell. Under surface similar to that of *P. peranthus*. In the ♀ the metallic area of the forewing is more uniformly rounded than in the ♂, also the submarginal spots of the hindwing above are larger and the under surface is paler. Earlier stages unknown. In the genitalia *P. lorquinianus* agress almost entirely with *P. peranthus*. As in the other Gloss-Papilios the metallic area assumes a deeper blue tone when the light falls obliquely from the front or side. Moluccas and Dutch New Guinea. — **lorquinianus** *Fldr.* (= philippus *Wall.* partim, ? apollodorus *Fruhst.*) (37 b). Greenish blue, the metallic area of the forewing does not quite reach the apex of the cell, but there are always a few metallic spots distally to the upper angle of the cell. Halmaheira, Ternate. — **gelia** *subsp. nov.* The black apical area of the cell of the forewing about twice as large as in the preceding form, the metallic area reaching at most to the 3. radial, also no metallic spots are placed at the distal side of the apex of the cell. Batjan. — **philippus** *Wall.* The metallic spots are more extended in both sexes than in *lorquinianus* and more greenish, the green submarginal macular band on the upperside of the forewing and the grey band on the underside are narrower. Ceram, very rare. From Obi, Buru and Amboina no form of *lorquinianus* is yet known. — **albertisi** *Oberth.* (37 a). Golden green, appearing blue when looked at sideways or from the front; the metallic area even larger than in *philippus*; the under surface very uniform dark brown, the light discal band of the forewing mostly only indicated. The pilose stripes are usually separated, except that the thin stripe of the submedian fold, if present, is always confluent with the lower median stripe. The ♀ not known. Dutch New Guinea: Andai and Kapaur.

lorquinianus. *gelia.* *philippus.* *albertisi.*

P. pericles *Wall.* (= hekaton *Fruhst.*, hermogenes *Fruhst.*, olympiodorus *Fruhst.*) (37 b). The blue metallic area always reaches beyond the apex of the cell of the forewing and is distally cut off straight as in *P. peranthus*, only in the ♀ the lower angle of the cell sometimes remains black. Upper surface of the hindwing with 5 or 6 blue submarginal spots, on the other hand the submarginal band of the forewing is only indicated by a very few blue and yellowish scales, whilst the deep black discal band is distinct. The pale discal band of the forewing beneath is placed distally to the subcostal fork and is proximally somewhat yellowish and almost entirely straight; the yellow lunules of the hindwing are deeper yellow than in *P. peranthus*, also the costal lunule is almost entirely orange-yellow. The pilose stripes of the ♂ are very variable; they are sometimes all very narrow and in that case are isolated. The genitalia are strikingly different from those of the preceding species. — The earlier stages not known. Distributed from Timor and Wetter to the Tenimber Islands: Dutch and Portuguese Timor, Wetter, Moa, Letti, Roma, Dammer, Babber and Tenimber (Selaru and Sjerra), probably also on the other islands of this group.

perieles.

Ulysses-Group.

The upper surface of the wings blue from the base to one-third or beyond, the forewing above distally pure black without metallic or pale scales; the submarginal spots on the underside of the hindwing yellow, proximally margined with blue or blue-grey and distally with black, the sequence of the colours consequently just the reverse of that in the *peranthus*-group.

P. ulysses. Upper surface in the ♂ velvety black, the forewing from the base at least to the apex of the cell and the hindwing to the middle of the disc or beyond glossy blue, mostly with greenish tinge; the forewing without a trace of metallic scaling in the black distal area, with long pilose stripes on the veins, which vary individually and geographically. Under surface blackish brown from the base to beyond the cell of the forewing and to about the middle of the disc of the hindwing, the distal part more or less distinctly yellowish; forewing with grey discal band, which is very broad anteriorly and gradually narrower posteriorly; hindwing with a row of submarginal spots which are lighter or darker yellowish and margined distally with black and proximally with white (or white and blue). The ♀ less deep black than the ♂, the blue area of both wings reduced, less densely scaled with blue, the hindwing above with blue submarginal spots. Under surface as in the ♂, but paler. The body of the larva divided by a straight whitish lateral line into a dark green dorsal and a greenish white ventral part; on the 4. segment a white transverse band which is laterally narrowed, being elongate-luniform, behind the band in the segment-incision a small black dorsal spot, from the 6. segment at each side a subdorsal white spot, of which the 3. is the largest; prothorax with 2 slight protuberances, penultimate segment with 2 long rough spines. On Citrus. Pupa beneath very strongly convex; head with two widely separated short smooth processes, thorax above feebly convex, without horn, but with slight central keel, which is continued almost to the tip of the abdomen, the abdomen also with lateral keel, the 3. abdominal segment the broadest, laterally not angular but rounded. The butterfly is found both in the woods and in open country and is especially fond of sunny river-beds, in which it flies high above the ground. The flight is undulating, the butterfly rising and

falling in rapid alternation. According to HAGEN the form from German New Guinea is very inquisitive and
morotaicus. was there the first butterfly which visited the flowers of the imported Lantana and Zinnia. — **morotaicus** *Rothsch.* ♂: the black spot at the apex of the cell of the forewing large, the blue scaling placed distally to the apex of the cell reduced, the pilose stripes broad, the posterior 3 or 4 joined together; the black margin of the hindwing between the veins much narrower than the discal part (placed distally to the cell) of the blue area, a blue stripe behind the 1. radial, joined to the blue area, an isolated blue streak behind the 2. radial, no blue streak at the
telegonus. two median veins. ♀ not known. Morty (= Morotai), 2 ♂♂ in the Tring Museum. — **telegonus** *Fldr.* (= ulysses *Westw.*) (39 a). ♂ as the preceding, but the black distal margin of the hindwing broader than its distance from the apex of the cell, two blue stripes at the median veins. ♀ paler than the ♂, the metallic area of both wings less extended and the metallic scaling less dense, the hindwing with blue-green submarginal patches. Batjan,
dohertius. Ternate and Halmaheira. — **dohertius** *Rothsch.* ♂: forewing as the preceding, but the blue at the apex of the cell less extended; the black distal margin of the hindwing somewhat narrower even than in *morotaicus*, without isolated blue stripe, but the blue area is produced into a tooth behind the 1. radial and into a streak behind the
ulysses. 2. radial. ♀ not known. Obi. — **ulysses** *L.* (♀ = diomedes *L.*) (38 a, b). ♂: the blue area on both wings more extended than in the preceding forms, on the forewing it almost entirely fills up the cell, the spot placed before the 3. radial is at least half as long as the cell is broad, the pilose stripes are spindle-shaped and do not usually touch one another; the blue area of the hindwing is dentate behind the 1. and 2. radials. The submarginal spots of the hindwing beneath are yellowish olive-colour, the anal spot purer yellow. The blue area of the ♀ on the forewing sometimes almost as extended as in the ♂, in other specimens on the other hand more or less strongly reduced, below the cell there are grey hairs, which in dark specimens form a large patch, commonly a large black spot is placed on the lower median in the blue area; hindwing with 6 blue submarginal arcs. Amboina, Ceram,
ampelius. Saparoea. — **ampelius** *Rothsch.* ♂ similar to the ♂ of *ulysses*, the pilose stripes narrower, the one placed on the submedian only indicated by a few small hairs. The marginal area of the forewing beneath (distally to the grey discal area) anteriorly broader and posteriorly narrower and the corresponding marginal area of the hindwing
oxyartes. broader than in *ulysses*. Buru, only 1 ♂ known to me. — **oxyartes** *Fruhst.* ♂: very similar to *autolycus*-♂ from New Guinea; the forewing beneath with grey spot in the cell, the brown marginal band narrow, the submarginal spots of the hindwing strongly reduced, the 2. to 4. very narrow, the yellowish olive-coloured central part of the 3. spot almost entirely suppressed. ♀ not known. Aru, only a few specimens in collections, the single example in the Tring Museum taken by H. KÜHN in August 1900. From the Key Islands no *ulysses*-form is yet known. —
dirce. **dirce** *subsp. nov.* ♂: forewing 32 mm long, narrower than in the following forms, the abdominal margin of the hindwing likewise longer in comparison with the size of the insect. Markings as in the usual form from New Guinea, but the black distal margin of the hindwing posteriorly broader; the brown distal margin of the hindwing beneath narrower and the submarginal spots strongly reduced. Misol; in the Tring Museum one ♂ taken by H. KÜHN
autolycus. in February 1899. — **autolycus** *Fldr.* (= penelope *Wall.*, physkon *Fruhst.*, eugenius *Fruhst.*, roxana *Fruhst.*, taxiles *Fruhst.*) (38 b). This form varies in all the localities so much that there seems to be no single character which is confined to specimens from any one district. ♂: the black spot at the end of the cell of the forewing usually isolated, but in many examples (as even in the type of *autolycus*) connected with the black distal area; the blue area of the hindwing is commonly produced into a streak behind the 1. and 2. radials. Beneath the cell of the forewing nearly always bears a distinct grey spot; the grey discal area of the hindwing does not reach the costal margin and the submarginal spots are much smaller than in *P. u. ulysses*, the first one especially is always incised and curved somewhat in comma-shape. The pilose stripes are mostly not contiguous, occasionally even the submedian stripe is absent, yet the 3 posterior ones in many specimens are so much widened as to touch one another. The examples from the islands in Geelvink Bay have somewhat rounder wings than specimens from other districts. The ♀ is very variable in the extent of the blue, but this is usually more extended than in *ulysses*, also the hairs behind the cell of the forewing are absent; the submarginal spots of the hindwing above are narrow as in *ulysses*, but less regularly curved; the under surface similar to that of the ♂, paler. The specimens with
conjuncta. transiens. melanotica. much blue are ♀-f. **conjuncta** *Hagen*, those with reduced blue ♀-f. **transiens** *Hagen*. Salawatti, Waigeu, the whole of New Guinea, Jobi and Mafor; at the coast and in the hills, common. — **melanotica** *Hagen*, from Dampier Island, only 1 ♀ known (in the Tring Museum). A very dark form, which recalls ♀♀ from the Solomon Islands. The green-blue scaling only fills up about half the cell of the forewing, and is also very strongly reduced below the cell, only the stripe placed at the hindmargin is as long as in normal New Guinea specimens; as in *ulysses* there is a paler hairy area behind the lower median. On the hindwing there is only a very little blue scaling before
telemachus. and distally to the cell. — **telemachus** *Montr.* (= telephanes *Fruhst.*). ♂: the black distal margin of both wings very broad; the blue area of the forewing does not usually extend quite to the apex of the cell and that of the hindwing does not mostly reach to halfway between the apex of the cell and the distal margin. But there are also specimens both on Trobriand and on Fergusson and Goodenough (from Woodlark so few examples are known that we know nothing definite as to the individual variation) which approximate closely to those from New Guinea. For these
agasophus. transitions the name ♂-ab. **agasophus** *Fruhst.* may be accepted. The ♀♀ vary as in New Guinea; the blue scaling is less dense than in *autolycus* and does not extend so far distally. The black distal margin of both wings is broader in the 2 ♀♀ from Goodenough than in the 3 ♀♀ from Fergusson and the 8 ♀♀ from Trobriand in the Tring Museum;
joësa. ♀♀ from Woodlark are not known to me. D'Entrecasteaux Islands, Trobriand, Woodlark. — **joësa** *Btlr.* (37 c),

from Queensland, is very similar to *autolycus*. The blue is always very extended in both sexes. The under surface is paler than in *autolycus*, the grey cell-spot is larger and the posterior part of the grey discal area of the forewing broader than in *autolycus*, also the submarginal spots of the hindwing are on the whole larger and more yellow and the grey central area is always very strongly developed. — **ambiguus** *Rothsch.* (= kallinikos *Fruhst.*, marius *Fruhst.*). A small race. ♂: the blue area of the forewing does not mostly quite reach the apex of the cell; even when a few blue spots are placed distally to the apex of the cell, the black discocellular spot is still connected with the black marginal area; the pilose stripes on the 2 median veins are confluent, commonly the last 4 stripes are united; the blue of the hindwing extends to about halfway between cell and distal margin. Beneath the cell of the forewing always bears a grey spot. ♀: the blue is somewhat more reduced even than in the ♂, especially at the apex of the cell of the forewing; the hindwing has above no blue submarginal spots or these are only feebly developed. Bismarck Islands: New Pomerania (= New Britain), New Lauenburg (= Duke of York), New Mecklenburg (= New Ireland) and New Hanover. Some of the statements made by Fruhstorfer with regard to the distinctions between specimens from different localities are erroneous and some of them completely contradict one another (cf. Iris 1907 p. 12). — **gabrielis** *Rothsch.* (39 a). A very peculiar large form with long wings. ♂: the blue darker than in the preceding subspecies, strongly reduced on both wings, on the forewing it only reaches to about the middle of the hindmargin and on the hindwing usually only somewhat beyond the apex of the cell, also the cell of the forewing is anteriorly very broadly black and the blue scaling of both wings less dense than in the ♂♂ of the other subspecies; the pilose stripes are very broad, the 4 posterior ones broadly connected. The submarginal spots of the hindwing beneath are very large and all nearly uniformly ochre-yellow. ♀ even less extended blue than in *melanotica*, the blue submarginal spots on the upperside of the hindwing larger, the two posterior ones (between tail and anal angle) strongly curved. The submarginal spots of the under surface as in the ♂. St. Gabriel, Admiralty Islands, collected by Webster in April. The fauna of the Admiralty Islands is still almost entirely unexplored on account of the hostile attitude of the natives. Captain Webster could not land on the main island and only collected for 2 days on the small island St. Gabriel, then he was obliged to take flight with his small schooner. — **nigerrimus** *Ribbe*. Somewhat larger than *ambiguus*, the under surface in both sexes darker, especially the marginal part, the submarginal spots lighter yellow, with more strongly blue proximal border. ♂: the blue somewhat more extended than in most *ambiguus*, no blue spots distally to the apex of the cell of the forewing, the grey scaling in the distal part of the forewing beneath very sparse. ♀: the grey scaling less dense and usually less extended than in *ambiguus*; the blue submarginal spots of the hindwing distinct, the anterior two or three mostly only represented by longitudinal streaks at the veins, the two posterior ones transverse, concave either only proximally or on both sides. Two principal forms: ♀-f. **cyanippe** *form. nov.*, the blue of the forewing reaches almost to the apex of the cell; ♀-f. **nigerrimus** *Ribbe*, the blue of the forewing very strongly reduced, usually not extending beyond the lower median. Bougainville and Shortlands Islands. — **orsippus** *G. & S.* (39 a). ♂: the blue of the forewing extends beyond the apex of the cell, but the black discocellular spot is still connected with the black distal area; the yellow in the 2. to 4. submarginal spots of the hindwing beneath usually suppressed by black, which is also sometimes the case in the 1. spot. ♀: the blue submarginal spots of the hindwing above smaller than in *nigerrimus*, sometimes only indicated; the grey scaling in the middle of the hindwing beneath proximally mostly condensed into a band; the 2. to 4. submarginal spots of the under surface sometimes black as in the ♂. Two principal forms: ♀-f. **hilaria** *form. nov.*, the forewing fairly uniformly scaled with blue nearly to the apex of the cell and the hindwing almost to the middle of the disc; ♀-f. **penthina** *form. nov.*, the blue on the whole somewhat more strongly reduced than in ♀-f. *nigerrimus*. I have before me: ♂♂ from Choiseul, Isabel, Guadalcanar and Florida; ♀♀ of the 1. form from Guadalcanar, of the 2. form from Isabel, and transitions between the two from Choiseul, Guadalcanar and Isabel. — **georgius** *Rothsch.* (= rothschildianus *Fruhst.*) differs from *orsippus* chiefly in that the grey scaling of the under surface is denser and the marginal area of both wings is so dark that the border of the forewing appears scarcely paler than the disc; also the yellow anal spot is more obliquely placed. The blue in the ♀ is about as much extended as in average specimens of *orsippus*-♀. In the Tring Museum 6 ♂♂ and 2 ♀♀ from Guizo, Kulambangra and Vella Lavella, captured by A. S. Meek.

ambiguus. *gabrielis.* *nigerrimus.* *cyanippe.* *orsippus.* *hilaria.* *penthina.* *georgius.*

P. montrouzieri *Bdv.* (= ulyssinus *Westw.*, chaudoiri *Fldr.*). Smaller than all the forms of *P. ulysses*, both wings more strongly sinuous between the veins, the forewing beneath with yellowish grey transverse bar in the cell and crescents of the same colour as proximal bordering to the grey discal area; the submarginal spots of the hindwing darker yellow than in *P. ulysses*. The genitalia are extraordinarily different from those of *P. ulysses*. The number of the pilose stripes in the ♂ and the extent of the blue in ♂ and ♀ are variable. The principal forms are: f. **ulyssellus** *Westw.*, the blue reaches in the ♂ to beyond the apex of the cell and completely encloses the small black discocellular spot; the pilose stripes are absent or feebly indicated, in the ♀ the blue reaches to or nearly to the apex of the cell of the forewing. f. **montrouzieri** *Bdv.* (37 c), the blue in the ♂ does not extend beyond the apex of the cell and extends in the ♀ about to the 3. medial vein, the pilose stripes are narrow but distinct. f. **westwoodi** *Oberth.*, the blue still more strongly reduced, the ♂ with 4 or 5 rather broad pilose stripes. — New Caledonia and Loyalty Islands.

ulyssellus. *montrouzieri.* *westwoodi.*

C. Kite-Swallowtails.

Antenna short, with powerful club, the upperside in fresh specimens scaled like the tibiae and tarsi, the fine sensory hairs almost uniformly distributed over the proximal part of the underside of each segment. The dorsal spines of the tarsi separated from the ventral ones by a spineless, somewhat impressed interspace. The wings in most species thinly scaled, semitransparent, especially in the costal part of the forewing; the green or bluish bands and spots on the upper surface mostly without scales, sometimes also on the under surface; the abdominal margin of the hindwing bent over upwards, provided with long hairs at the margin, inside the fold usually yellowish scent-wool (♂); the cell of the hindwing mostly narrow, its costal margin incurved between the subcostal and 1. radial. With the exception of *P. payeni*, *gyas*, *hercules* and *leosthenes*, as also *podalirius*, the 1. subcostal of the forewing in the Kite-Swallowtails of the Old World runs into the costal, in some species the 2. subcostal is also united with the costal vein. The young larva with forked hairs; full-grown in the Indo-Australian forms so far as is known with a pair of short spines on each of the three thoracic segments and the last segment, the thorax swollen. Pupa smooth, in the middle rounded in barrel-shape, the wing-cases not projecting, the thoracic horn four-sided, the lateral carinae forming the prolongation of the upper edge of the wing-cases; on the dorsum two carinae, converging anteriorly and posteriorly; the anal segment longer than broad. — Most of the Kite-Swallowtails are long-winged and long-tailed, yet there are many species, especially mimetic, in which the hindwing is rounded and has no tail. They are all good fliers and occur in wooded districts; the mimetic forms imitate the slow flight of their models. The ♂♂ often rest together in crowds at wayside puddles and on the moist sand of river-banks and can mostly be attracted by urine and the like. The ♀♀ are taken singly in the woods.

Antiphates-Group.

Wings white with black bands, which on the forewing are perpendicular to the veins; on the under surface of the hindwing a subbasal band parallel with the abdominal margin and a median band, which approach one another at the apex of the cell or are connected there; tail long, gradually pointed. Except in *P. leosthenes* the 1. subcostal of the forewing runs in tothe costal vein.

P. eurous. Body above black, with long grey hairs, beneath grey, with black stripes on the yellowish underside of the abdomen. Forewing semitransparent, with ten black bands, the extreme base also black, the 1. and 2. band, as well as the four distal, partly united bands usually reach the hindmargin; upper surface of the hindwing with black anal area, which is spotted with grey-blue and from which the black lines run out costad, at the anal angle a yellow double spot, the cell narrower than in the following species; under surface of the hindwing with two parallel oblique median lines, between which a number of yellow spots are placed. The full-grown larva green, dotted with black, the pronotum with yellow transverse band, which is laterally continued to the anal segment, the three thoracic segments each with a pair of black spines, the anal process yellow with black tip, curved laterad. Pupa slender, green, with four yellow lines. Food-plant: Machilus odoratissima, a Laurineae on which the larvae of many Kite-Swallowtails live. Probably only one brood. The butterflies fly from the spring until July; like many Kite-Swallowtails they are fond of resting on the tops of trees, round which they circle in swift flight. In North India they occur from about 3—7000 ft., but ascend higher in China. Kashmir to Assam and Formosa. — In West and Central China flies **eurous** *Leech* (cf. vol. I, 8 a). From eastern and southern China no form is yet known. — On the other hand a broad-winged form, with broad black bands, occurs on Formosa: **asakurae** *Mats.* Originally described from a specimen with the tails broken off. The black bands in the marginal area of the hindwing are especially much broader than in the Chinese form. — **sikkimica** *Heron* (= sikkima *Moore*, glycerion *Rothsch.*) (40 a). Broad-winged; the hindwing above without black median band, also the subbasal band only present towards the costa and very narrow. Assam, Sikkim, Nepal. — **caschmirensis** *Rothsch.* (vol. I, 8b). The upper surface of the forewing is more extensively scaled with white, the yellow spots of the hindwing above and beneath are paler and the two black median lines on the underside of the hindwing are thinner and hence further separated than in *sikkimica*. Kashmir and North-West India.

eurous. *asakurae.* *sikkimica.* *caschmirensis.*

P. glycerion. Under surface of the hindwing at the costal margin and at the apex of the cell with a black-edged spot, which are united into an 8. The earlier stages are unknown. In its habits the butterfly resembles the preceding species, but appears to ascend somewhat higher in the mountains. Distributed from Nepal to Upper Burma as well as West and Central China. — The Chinese form is **mandarinus** *Oberth.* (see vol. I, 8 a, b), which also occurs in Yunnan. The subbasal line of the hindwing above not interrupted behind the cell. — **glycerion** *Gray* (= paphus *Nicév.*) (40 a). The forewing in the cell and distally to it less densely scaled with white than in *mandarinus*, hence more transparent, the subbasal band of the hindwing always interrupted behind the cell, the median line very thin and short. Nepal, Sikkim, Assam, Upper Burma.

mandarinus. *glycerion.*

P. alebion. Under surface of the hindwing with only one black median line, at the distal side of which is placed a yellow costal spot, usually bordered with black distally; the cell of the hindwing broad. The earlier stages unknown. — *tamerlanus Oberth.* (see vol. I. 8 a) flies in West and Central China. — **alebion** *Gray* (see vol. I, 8 a) occurs in East China (Kiukiang and Foochow). Both wings are narrower than in *tamerlanus*; moreover in the ♂ the yellow anal spot is not divided either above or beneath. The only example known to me from Foochow

alebion.

is a ♀ (I have seen no other ♀♀ of *P. alebion*); it agrees in the shape of the wings with *al. alebion*, on the other hand the anal spot is small and constricted as in *tamerlanus* and the yellow costal spot of the hindwing beneath narrow and prolonged to the cell; possibly this ♀ belongs to a south-eastern subspecies.

P. agetes. Body above black with light lateral line, beneath yellowish white, head and pronotum reddish. Wings white with black bands; hindwing with black distal margin, which encloses some white spots, and with red anal spot, tail thin, black with white tip. Under surface like upper, but hindwing with black subbasal band parallel with the abdominal margin and with black median band in which red spots are placed. The ♀ similar to the ♂, with somewhat broader wings. The earlier stages unknown. The butterfly flies in the hills in wooded districts. The ♂♂ congregate at wayside puddles and on the moist sand of river-banks. North India to Sumatra, Borneo and Hainan. — **agetes** *Westw.* (= tenuilineatus *Fruhst.*). The 1. and 2. band of the forewing always extend beyond the hindmargin of the cell. Sikkim, Bhutan, Assam, Burma, Tenasserim, Shan States, Annam, Tonkin, Hainan. — **iponus** *Fruhst.* The 2. band of the forewing somewhat shorter than in the preceding form. Malay Peninsula. — **insularis** *Stgr.* (41 c). The forewing in the cell more densely scaled with white than in *agetes*, the 2. band on the upperside does not extend beyond the cell; the black markings of both wings deeper black, especially beneath. In the Battak and Gayoe Mountains of Sumatra, not below 3000 ft., very common. — **kinabaluensis** *Fruhst.* The interspace between the black submarginal band of the forewing and the apex of the cell is much broader than the submarginal band. Kina Balu, North Borneo.

agetes. *iponus.* *insularis.* *kinabaluensis.*

P. stratiotes *Grose-Smith* (41 b). The three outer black bands of the forewing very much broader than in *P. agetes*, the transparent submarginal interspace reduced to a line; the hindwing above before the distal margin grey, with very large red anal spot. The under surface of the forewing yellowish, the subbasal and the median band narrow, straight, the latter without red spots, the red anal spot large. The ♀ similar to the ♂. The earlier stages unknown. — Kina Balu, North Borneo.

stratiotes.

P. leosthenes *Dbl.* (40 a). Except *P. podalirius, payeni, gyas* and *hercules* the only Kite-Swallowtail of the Old World in which the 1. subcostal of the forewing runs free into the costal margin. Body above black, with grey hairs, with a lateral stripe on head and thorax, beneath grey; antenna beneath yellowish, legs pale green. Wings semitransparent, white with brownish black bands (cf. figure); the median band of the hindwing beneath with yellow spots, of which the posterior 4 are also developed above. The ♀ very similar to the ♂. — Queensland.

leosthenes.

P. nomius. Very nearly allied to *P. aristeus*. But as *nomius* occurs in North India, Burma and Siam together with *P. aristeus* and is sharply differentiated from it in the genitalia, we entertain no doubt that it is a separate species. The wings are somewhat broader than in *P. aristeus*; the anterior submarginal spots of the forewing are rounded, the black median band of the hindwing above is always well developed, the 1. and 2. brown bands of the forewing beneath are blackish at the costal margin, also the parts of the 2. and 3. bands placed behind the cell are deeper black than in *P. aristeus*. The full-grown larva above usually black with white transverse stripes, beneath green, the anterior and posterior segments yellowish, sometimes the larva entirely green; on each of the thoracic segments and the anal segment a pair of spines. On Saccopetalum tomentosum and Polyalthia longifolia. The pupa not on the food-plant, but under stones, in crevices and under the roots of trees; earth-coloured, with short thoracic horn, directed forwards, and somewhat produced angles to the head; pupal stage lasts in South India from July to March or even May. The butterfly is a very common lowland species, in some years and at certain places extremely abundant. The ♂♂ often in crowds at wayside puddles; they also visit flowers. — **nomius** *Esp.* (= ? orestes *F.*, meges *Hbn.*, niamus *Godt.*). The 3. band of the forewing does not extend beyond the cell; the anal part of the hindwing is plentifully dusted with white; the under surface of the forewing without short black costal line near the base. Ceylon to Bengal, single stray specimens in low-lying places in Sikkim. — **swinhoei** *Moore* (= pernomius *Fruhst.*) (41 c). The 3. band of the forewing and commonly also the 4. extend beyond the hindmargin of the cell; under surface of the hindwing with black subbasal streak at the costal margin. In most of the examples from Assam, Burma, Tenasserim, Siam and Annam, and also in the single specimen before me from Tonkin, the under surface is much lighter yellow than in the preceding form, in single examples from these districts taken at the same time, however, and in all the specimens from Hainan, the under surface is as dark as in *nom. nomius*. Singly in Sikkim and Assam (migratory specimens?), common in Burma, Tenasserim and Hainan, from Tonkin only a few examples yet known.

nomius. *swinhoei.*

P. aristeus. Body beneath white, above black with light longitudinal stripe at each side. Wings white, above with black, beneath with brown bands. Forewing with 7 bands, of which the 3.—5. are abbreviated and the 4. is sometimes absent; the 5. commonly united with the 6. at the lower angle of the cell, the 6. and 7. form a broad marginal area, which encloses a submarginal row of white spots. Hindwing with subbasal and median bands, which run parallel with the abdominal margin, the median band sometimes only indicated, the distal

margin black with white submarginal spots, of which the posterior three or four are very thin and lunular. Under surface of the forewing like the upper, the bands posteriorly blackish; the median band of the hindwing from the costal margin to the anal angle with red (rarely yellow) spots, at the distal side of which are placed black spots. Although this species occurs from North India to the Bismarck Islands and North Australia in numerous subspecies and in many districts is very common, nothing is yet known as to the earlier stages. The butterflies are found in wooded districts at low elevations; on account of their high and rapid flight they are not easy to

anticrates. catch, but they sometimes rest in considerable numbers at wayside puddles and river-banks. — **anticrates** *Dbl.* (41a). The white discal area of the forewing above is scarcely broader at the lower median than the black distal margin, but there are also examples in which it is narrower than the margin; the median band of the hindwing above mostly interrupted, sometimes broad and complete, but never broader anteriorly than the white discal band

hermocrates. placed at its distal side. Sikkim, Assam, in the spring, only one brood. — **hermocrates** *Fldr.* (= pado *Fruhst.*) (41 a). Connected with the preceding subspecies by all the intermediate gradations; many examples have as much white as the lighter *anticrates*; in general, however, the black bands are more extended than in the North Indian form. The genitalia are slightly different. Examples with narrow white discal area on the forewing are

aristeoides. ab. **aristeoides** *Eimer* (= aristinus *Fruhst.*), and specimens in which the cell of the forewing bears only three white bands and the white submarginal band of the forewing and the white discal band of the hindwing are posteriorly

nigricans. abbreviated, are ab. **nigricans** *Eimer.* It appears to me impossible to divide *hermocrates* into further local races, at least I can find no character by which the examples from any one locality may be recognised. The greater number of the examples from Palawan have a broad white discal band, but there are also specimens on Palawan in which the white bands are quite as strongly reduced as in those from Kalao and Wetter and the dark Sumba specimens. On the other hand there are also on Sumba both light examples which resemble the light specimens from Palawan and Luzon, and dark ones, which cannot be distinguished from Kalao and Wetter examples. I have the butterfly before me from Burma, Tenasserim, the Shan States, Siam, Langkawi Island, the Malay Peninsula, North-East Sumatra, Borneo, Palawan, the Philippines, Kalao, Sumba, Timor, Wetter and Dammer. From

aristeus. Java it is not yet known and on Sumatra also only a few examples have been found. — **aristeus** *Cr.* (= aristaeus *Godt.*) (41 a). The white discal band of the forewing above narrower at the lower median than the black distal margin; on the hindwing this band reaches to the 3. radial, but the last spot of the band is very small, sometimes only indicated. Under surface brown-black, much darker than in *hermocrates* and *anticrates*. Amboina, Ceram. —

timoerates. **timocrates** *Fldr.* The white discal band on both wings broader than in *aristeus*, the last spot of the band on the hindwing especially larger, there are also always three white spots on the underside of the hindwing between the 3. radial and the 1. median, namely distally a thin crescent, further proximally a diffuse spot and between this and the red median band a proximally concave spot; the latter is absent in *aristeus* or is only just indicated.

bifax. Halmaheira, Batjan, Mount Mada on Buru. — **bifax** *Rothsch.*, from Obi, was described from a single ♂. The white discal band of both wings is even broader than in *timocrates* and the black median band of the hindwing

parmatus. above is for the most part dusted over with white. Probably these differences are not constant. — **parmatus** *Gray* (= pherecrates *Fldr.*, guineensis *Grose-Smith*) (41 a, b). Similar to *timocrates*; the white discal band of both wings still broader, the black median band of the hindwing above for the most part dusted over with white, yet in some examples the band is entirely black; anal area of the hindwing more strongly dusted with white than in *timocrates*; the white spots of the discal row placed between the 2. radial and the abdominal margin larger than in *timocrates*, mostly connected. Distinguishable from the Indian *anticrates* by the deeper yellow spots of the pronotum, the dark under surface and the genitalia. Aru, Waigeu, Dutch, German and British New

paron. Guinea, Queensland. — **paron** *Godm. & Salv.* The black median band on the upperside of the hindwing dusted over with white, beneath on the other hand very broad, with yellow instead of red spots. New Pomerania (= New Britain). New Mecklenburg (= New Ireland).

P. rhesus. Larger than *P. aristeus*, the wings narrower, the forewing strongly falcate. The black bands very broad, but the subapical band of the cell of the forewing is absent or very narrow, so that the 4. and 5. white bands of the cell are confluent and form a continuation of the narrow and obliquely placed white discal band. *P. rhesus* is a Celebes edition of *P. aristeus*; it is curious that the butterfly was treated by Eimer as a near relative of American species (*P. marcellus*, *philolaus*, etc.). The earlier stages are unknown. The ♀ is rarely taken, on the other hand the ♂ is very common, especially in the neighbourhod of rivers and brooks. Like all the allied species the ♂♂ often rest in crowds in moist places by river-banks and at the wayside and can be attracted by

rhesus. placing dead specimens with the wings spread out on the sand. — **rhesus** *Bdv.* (= celtibericus *Bdv.* indescr.) (41 a). The veins inside the white discal band of the forewing nearly always entirely black; the white discal band of the hindwing narrow, often broken up into spots. North and East Celebes, Buton. The erroneous statement of Fruhstorfer that Boisduval described the under surface

rhesulus. as black, rests on a confusion of „dessus" with „dessous". — **rhesulus** *Fruhst.* The greenish white submarginal and discal bands in most examples somewhat broader than in the preceding form, also the red

rhaphia. spots on the under surface of the hindwing usually somewhat larger. South Celebes. — **rhaphia** *subsp. nov.* The light bands somewhat broader even than in *rhesulus*, the short band placed distally to the apex of the cell of the forewing longer, usually connected with the discal band by a thin streak below the apex of the cell;

the submarginal line of the forewing above and beneath broader. The under surface paler brown than in the two preceding forms. Djampea, also on Tomia (Toekan-Bessi Islands), 12 ♂♂ and 1 ♀ in the Tring Museum.

P. dorcus *Dehaan* (41 c). In the markings of the hindwing beneath and also in structure nearly allied to *P. rhesus* and *P. aristeus*, on the other hand in size and shape and in the markings of the upper surface similar to *P. androcles*. Body above black with light lateral stripe, beneath white. Forewing black with 3 white bands, in the broad median band sometimes a thin black costal stripe; hindwing for the most part white, with black band near the base and in the middle and black markings in the marginal area, tail very long. Under surface of the hindwing with red spots in the black median band, which are very similar to those of *rhesus*. The ♀ similar to the ♂. The earlier stages unknown. — North Celebes, rare. *dorcus.*

P. androcles *Bdv.* (41 b). An enlarged edition of *P. euphrates*. Considerably larger than all the forms of *P. euphrates* and *P. antiphates*. Wings white, greenish towards the base; on the forewing the apical half and 3 bands, on the hindwing a subbasal and a median band as well as patches in the marginal area black, the tail very long; in the black apical area of the forewing a submarginal and a short discal line, both greenish. Beneath much as above, the hindwing with more numerous black patches, more sharply developed bands and with diffuse yellow patch behind the 3rd radial. The ♀ similar to the ♂. The earlier stages unknown. — North, East and South Celebes, not rare in wooded districts near water-courses. Unquestionably one of the most elegant butterflies of the Indo-Australian region. *androcles.*

P. antiphates. Body above black with light lateral stripe, or the abdomen entirely white, under surface white with black lateral stripe. Wings white, the forewing above and beneath greenish towards the costa, as also the basal half of the hindwing beneath; forewing with seven black bands. Hindwing above with black marginal spots and a complete or incomplete row of black submarginal spots, either only the posterior part of the marginal area dusted with grey-black, or the whole margin broadly grey-black. On the under surface of the forewing the following black markings are present: before the abdominal margin a stripe which is anally united with a subbasal stripe, in the middle of the wing a double band, longitudinally divided by the ground-colour, the distal half of which is broken up into spots, a row of submarginal and a row of marginal spots, the submarginal spots shaped like the figure 3, at their proximal side yellow patches, which are for the most part indistinctly defined. The ♀ similar to the ♂. The larva at first yellowish or white with forked hairs and usually dark transverse lines; when full-grown green with two yellow transverse bands on the thorax, a yellow lateral line running from the head to the tail and dark green dorsal lines; or the ground-colour more bluish green and the markings white. On Anonaceae, e. g. Unona lawii. Pupa pale green, with yellow lateral line, thoracic horn short. The butterfly is mostly very common in the wooded districts of its area of distribution at lower elevations; the ♂♂ congregate in crowds at puddles and the edges of brooks, where they drink in company with Pierids. The ♀♀ are taken singly in the woods. On the wing *antiphates* gives the impression of a Pierid, as the long tails are scarcely noticeable during its swift flight. Distributed from China to Ceylon, North Borneo and the Lesser Sunda Islands. — **antiphates** *Cr.* (= antipates *Jabl. & Hbst.*) (40 b, c). A large form; the 1st band of the forewing reaches to the hindmargin and the 2nd nearly to the submedian vein or beyond it, the black submarginal spot placed behind the 3rd radial of the hindwing large. South-East China, Tonkin. — **pompilius** *F.* (= continentalis *Eimer*, linga *Fruhst.*). The black markings on the whole less extended than in the preceding form; very variable. Hainan, Annam, Siam, Tenasserim, Burma, Assam, Sikkim. In North India occur single melanistic specimens (the Tring Museum possesses 4 such examples), in which the forewing above and beneath and the under surface of the hindwing as well as the distal margin of the upper surface are more or less completely dusted with black, with the exception of the greenish white bands in the anterior part of the forewing: ab. **nebulosus** *Btlr.* (40 d). — **naira** *Moore.* Large, the two distal bands of the forewing are confluent posteriorly and reach the hindmargin as in *P. epaminondas*; the marginal spots of the hindwing are larger and the grey-black dusting is more extended than in the preceding forms. South India; not common. — **ceylonicus** *Eimer* (= antiphanes *Fruhst.*). Very similar to *pompilius F.*, on the forewing the marginal band reaches to the hinder angle, the submarginal band above and beneath to the lower median vein, the subbasal band is of uniform width and reaches the hindmargin, whilst the second band extends to the submedian; the anal area of the hindwing above and the anterior part of the hindwing beneath are paler than in *pompilius*. Ceylon; rare. — **itamputi** *Btlr.* (= poetus *Fruhst.*) (40 b) is distinguished from *pompilius* chiefly by the deeper and more extended yellow distal area of the underside of the hindwing. Malay Peninsula, Langkavi, Straits Settlements, Sumatra, Natuna Islands, Borneo, Banguey. In a ♂ from North-East Sumatra in the Tring Museum the 2nd and 4th black bands on the forewing are absent, moreover the greenish submarginal band is partly united with the discal band and the forewing has a continuous black marginal line: ab. **leucania** *ab. nov.* (32 c). — **antiphonus** *Fruhst.* has somewhat larger black submarginal spots on both sides of the hindwing than *itamputi*. Nias. — **alcibiades** *F.* (= javanicus *Eimer*) (40 b). The distal black bands of the forewing narrower than in *itamputi*; the anal part of the hindwing above much deeper black, the tail distinctly white at the tip only, the distal part of the hindwing beneath less yellow. Java. — **balius** *subsp. nov.* The black submarginal band of the forewing is posteriorly broadly united with the marginal band, extends above beyond the lower median and beneath almost reaches this vein; the hindwing as in *alcibiades*, but the black marginal area much broader and extended costad to the

antiphates. *pompilius.* *nebulosus.* *naira.* *ceylonicus.* *itamputi.* *leucania.* *antiphonus.* *alcibiades.* *balius.*

2nd black marginal spot; the black patches on the underside of the hindwing larger. Bali, only 1 ♂ in the Tring
kalaoensis. Museum. — **kalaoensis** *Rothsch.* Forewing as in *alcibiades*, on the other hand the anal area of the underside of the hindwing blackish grey, so that the black submarginal spots in it stand out distinctly. Kalao, Djampea, Sumbawa, Flores.

epaminondas. **P. epaminondas** *Oberth.* (= laestrygonum *Wood-Mas.*) (40 d). As large as the largest *antiphates*; the black bands broad, the 1st and 2nd on the under surface of the forewing always reaching the hindmargin, the black median band of the forewing more or less developed above also; the yellow patches of the hindwing beneath more sharply defined than in *P. antiphates*, the light submarginal spots and also the ground-colour at the distal side of the median band and inside it white. The ♀ very similar to the ♂. The earlier stages unknown. — Andamans.

P. euphrates. Confusingly similar to *P. antiphates* in the markings, constantly differing in that the anterior 3 or 4 submarginal spots on the under surface of the hindwing are not elbowed, but straight. Moreover the genitalia are strikingly different. As *P. euphrates* occurs in North Borneo and on Banguey at the same time and in the same localities with *P. antiphates*, there is not the slightest doubt that we are dealing with forms which have become independent, i. e. species. The earlier stages are not known. North
decolor. Borneo to Philippines. — **decolor** *Stgr.* (= palawanicus *Eimer*). The 1st black band of the forewing thin, the 4th always abbreviated, sometimes absent; the black marginal line of the hindwing broad, the black-grey anal area reaches to the 2nd radial. In distinction from *P. antiphates itamputi* the inner part of the black median band on the under surface of the hindwing is not prolonged beyond the cell or the spot of this line placed
domaranus. below the apex of the cell is only indicated. North Borneo, Banguey, Palawan. — **domaranus** *Fruhst.* On Domara, one of the small islands off the east coast of Palawan, the butterfly is dimorphic, as apparently also on some of the Philippines proper. In the light form, to which the name *domaranus* belongs, the 4th band of the forewing is broad and reaches the hindmargin of the cell, the marginal band extends to the hindmargin of the wing, the black submarginal band on the other hand is narrowed from the basal side in such a way that at the costal margin a short black projection remains between this band and the discocellular one; hindwing similar to that of *decolor*. The second form, according to Semper, agrees entirely with dark
atratus. Luzon specimens (*euphrates*), i. e. has a broad black marginal band on the hindwing. — **atratus** *Rothsch.* The bands of the forewing and the marginal band of the hindwing are very broad; upper surface of the hindwing with black subbasal stripe. The anterior yellow spots of the hindwing beneath indistinct, the posterior ones on the other hand large. A light form is not known. On Mindoro, and according to Semper on Bohol. —
euphrates. **euphrates** *Fldr.* (= moorei *Reak.*) (40 c, d). The 1st band of the forewing extends to the hindmargin, the 4th always to the hindmargin of the cell, the submarginal band broadly united posteriorly with the marginal band and continued to the hindmargin; hindwing broadly bordered with black to the costal margin, this marginal band in the ♀ somewhat paler than in the ♂. The yellow spots on the under surface of the hind-
nisus. wing all rather sharply developed. Central (and South?) Luzon. — **nisus** *subsp. nov.* In North Luzon flies a dimorphic subspecies which is less extended black. Semper mentions a ♀ from there and the Tring Museum possesses two ♀♀ taken by J. Whitehead. In these specimens the 4th band of the forewing does not reach the hindmargin of the cell, and the marginal band of the hindwing is paler and does not extend to the costal margin. The marginal band of the forewing is posteriorly pointed. The specimens differ from *decolor* and *euphratoides* by the much larger black submarginal spots on both sides of the hindwing. The three examples belong to two strikingly different forms (seasonal forms?), which differ in almost exactly the same way as the two forms known from Mindanao. In the light form, f. *nisus*, the 1st and 2nd bands of the forewing are thin and scarcely extend beyond the hindmargin of the cell, the white band placed distally to the apex of the cell is broadly connected with the white disc, the blackish grey anal area of the hindwing above is narrow and only reaches to the 2nd radial, yet between this vein and the costal margin there are 3 rather large black
zebraica. submarginal spots. The second form, f. **zebraica** *form. nov.*, which corresponds in all respects to f. *tigris Semp.* from Mindanao, is considerably larger than f. *nisus*, the 1st band of the forewing extends to the hindmargin and the 2nd terminates just before the margin, the black submarginal band is broader than in the light form and at the lower angle of the cell joined to the black discocellular band by a black vein-streak; the black-grey marginal area of the hindwing is broader than in *euphrates*, lighter, and only extends about to the subcostal; the black subbasal line is indicated above; the black dorsal stripe of the abdomen is very broad,
euphratoides. whilst in f. *nisus* it is only indicated. — **euphratoides** *Eimer* flies on Mindanao and Bazilan. The 4th band of the forewing is nearly always abbreviated, the black submarginal band does not reach the lower median, and the marginal band, which is pointed, does not extend to the submedian; the grey dusting in the anal area of the hindwing is even less extended than in *nisus*, the black submarginal spots of the hindwing beneath are thin and the anterior ones are entirely absent above; the distal area more yellowish than in *euphrates* and *nisus* and the yellow patches are more diffuse. The light form, f. *euphratoides Eimer*, is small, the grey anal area of the hindwing above very narrow, the fringes are more extended white than in *decolor*, the tail
tigris. is broadly margined with grey. Of the second form, f. **tigris** *Semp.*, only 1 pair was obtained by Semper; it is considerably larger than f. *euphratoides*, the 1st band of the forewing reaches the hindmargin and the 2nd extends almost as far, the subbasal band of the hindwing is indicated above, and the grey anal area, which

extends to the 2nd radial, is about twice as broad as in f. *euphratoides*. — **ornatus** *Rothsch.* (40 c). Fore- *ornatus.*
wing more densely scaled with white costad than in the preceding forms, hence less greenish; the 1st band of the forewing only indicated, none of the bands of the cell extend beyond its hindmargin, the distal border of the hindwing is deep black, narrowed costad; on the under surface of the hindwing the black markings in the distal half very large, the posterior yellow spots margined with black. Halmaheira; only ♂♂ known to me. — As in *P. antiphates*, the geographical forms in *P. euphrates* are also mostly somewhat different in the structure of the genitalia.

Payeni-Group.

The subcostal veins of the forewing free, the 3rd arising before the apex of the cell, the 2nd discocellular deeply incurved. The claw of the tarsi with tooth in or behind the middle. The wings densely scaled, for the most part yellow-brown or black-brown. The scent-fold of the hindwing of the ♂ weakly developed. — Distributed from China to the large Sunda Islands; only two species. The tooth of the claw is a very peculiar character, which is again indicated in *P. macleyanus* and *gelon*.

P. gyas. Strongly dimorphic sexually. ♂: body greenish, the head and the underside of the thorax chestnut-brown; the wings above dark brown, the broad dark distal margin with a row of yellowish spots, similar spots also on the disc of the forewing. Under surface with large chestnut-brown basal area, a spot at the apex of the cell of both wings and the anal area of the hindwing of the same colour; the middle of both wings white-grey with dark crescents, the hindwing with light, dark-edged submarginal spots, which are only indicated on the forewing; the tail spatulate. ♀ with broad white median band, which on the forewing becomes yellow costad and is here more or less distinctly broken up into patches, whilst it has a bluish tone on the hindwing. The submarginal spots larger than in the ♂; the tail broadly margined with light chestnut-brown. From Sikkim to Tenasserim, in wooded mountain districts at a height of 6—7000 ft., commonest in the Khasia Hills. The earlier stages are not known. — **gyas** *Westw.* (= lachinus *Fruhst.*) (39 c) *gyas.*
occurs in Sikkim, Bhutan and Assam (Garo, Khasia and Naga Hills). The specimens from Sikkim are distinguishable according to Fruhstorfer, but the characters given by him are not confirmed by the series in the Tring Museum (2 ♂♂ and 5 ♀♀ from Sikkim, 6 ♂♂ from Bhutan, 13 ♂♂ and 5 ♀♀ from Assam). — **aribbas** *Fruhst.*, erected from a ♂ from Upper Burma, is distinguished according to the author by the weaker *aribbas.*
development of the middle and posterior spots of the forewing and the lighter colour of the central area on the under surface of both wings. — *gyas* also occurs in Tenasserim (according to Hauxwell), but I have not been able to compare any specimens from there. — This species is represented in China by *P. hercules Blanch.* (= sciron *Leech*, porus *Streck.*) (vol. I, 8 b). Strecker erroneously describes *porus* as from the Garo Hills in Assam.

P. payeni. Body and ground-colour of the wings ochreous yellow, above with slightly greenish tone; vertex and collar as well as the greater part of the cell of the forewing above yellow-brown. The tooth of the claws large. Forewing with strongly produced apex, the distal margin of both wings broadly brown-black with yellow spots; on the forewing a discocellular patch and a transverse spot in the cell likewise brown-black; hindwing narrower than in *gyas*, much more triangular, without distinctly marked anal angle. Beneath on the whole lighter than above, the basal area of both wings with a brown band broken up into spots, the distal third commonly darker than the middle of the wing, always with brown lines and rows of spots, which are often confluent, on the disc of the hindwing a number of silver spots. The ♀ paler than the ♂, with broader wings and smaller dark markings. The earlier stages are unknown; the butterfly in the mountains at medium elevations. Distributed from Sikkim and Hainan to Java and Borneo. — The largest form is **evan** *Dbl.* (= evanides *Fruhst.*) (39 b), from Sikkim, Bhutan and Assam. The hindwing bears above *evan.*
4 yellow discal spots, of which the 1st is placed behind the 2nd radial. The butterfly is very rare in Sikkim, but rather common in the mountains of Assam. It appears to fly in at least 2 broods; the spring specimens have the dark markings somewhat reduced. — **amphis** *subsp. nov.*, from Tenasserim and Burma, resembles *amphis.*
the Malayan forms, but the dark markings are less black; upper surface of the hindwing with 5 yellow discal spots, of which the 1st is lunular and placed behind the 1st radial; at the proximal side of the 4th spot there is a distinct yellow spot. The ground-colour of the under surface as in the Malayan forms darker than in *evan*, the dark markings in the distal area of both wings sharper and narrower, the submarginal line almost without interruption, the silver spots larger than in *evan*, and the brown subbasal transverse patch behind the costal is placed nearer to the corresponding costal spot than to the precostal vein. — **langsonensis** *Fruhst.*, from *langsonensis.*
Tonkin, is paler yellow than any other subspecies, on the other hand the costal margin of the forewing and the distal margin of both wings are deeper black, the yellow spots in the dark border are small, the hindwing bears 4 small, sharply defined yellow discal spots. Beneath the marginal area of both wings is deeper brown than in *evan*. — **hegylus** *subsp. nov.* A small form from Hainan, of which a pair taken in May are in *hegylus.*
the Tring Museum. Ground-colour as in *evan*, the dark marginal area somewhat reduced from the proximal side, the yellow spots placed in it not larger than in summer specimens of *evan*, the brown-black spot placed in the apex of the cell of the hindwing much smaller; the hindwing with a row of 5 discal spots, to which in the ♀ is added a 6th spot situated at the proximal side of the 4th. Beneath as in *evan*, but the brown markings on the whole more feebly developed, especially the spots at the apex of the cell of both wings are smaller.

ciminius. — **ciminius** *Fruhst.* ♂: ground-colour above and beneath darker than in the preceding forms and above less extended in consequence of the darkening of the base of both wings, also the costal margin of the forewing is deep brown-black and there are no light markings in and before the subcostal fork. The brown markings of the under surface are on the whole thinner than in *evan*; the ground-colour of the distal area is almost uniform red-brown and contrasts with the lighter discal area. The ♀ not known. East and West Sumatra,

brunei. Malay. Peninsula. — **brunei** *Fruhst.* ♂ as the preceding, but the ground-colour of the marginal area of the under surface paler, hence less distinctly contrasted with the disc. The ♀ differs from that of *evan* principally in the absence of light spots before the subcostal fork on the upperside of the forewing and the reduction of the black markings on the upperside of the hindwing, and also in the darker ground-colour of the under

payeni. surface. North and South-East Borneo. — **payeni** *Bdv.* ♂ as in *brunei*, but the upper surface of the forewing with 3 yellow patches in the marginal cell placed behind the subcostal fork. The anterior silver spots of the hindwing beneath less well developed in both sexes. In the ♀ the dark border of the upperside of the forewing somewhat weaker at the costal margin than in the ♀ of *brunei*. Java.

Codrus-Group.

The 1st subcostal of the forewing runs into the costal vein. Body robust, without light stripe at each side of the back, tail broad, obtuse. Wings for the most part black, green-black or brownish black-grey, at least in the costal area of the forewing with green spots, under surface of the hindwing in the basal half without red or yellow spots, at most the costal margin is very narrowly red. The claws in some species with tooth, as in the *payeni*-group.

gelon. **P. gelon** *Bdv.* (44 c, d). Nearly allied to *P. macleayanus*. Body above greenish black, beneath dirty grey-yellow, legs green, claws with small tooth; antenna beneath yellow-brown. Upper surface of the wings black, with green markings; forewing with a band of 4 spots before the base of the 3rd radial running straight to the hindmargin, a spot in the apex of the cell and two spots behind the cell, all these spots often very small and sometimes only partly indicated; hindwing without tail, with narrow band before the middle. Under surface much paler, the veins in the distal area green, the band of the hindwing white and the costal margin red at the base; forewing with some white submarginal spots. ♀ paler than the ♂, the forewing with yellowish submarginal spots, on the hindwing some similar small spots, which are placed at a distance from

megasthenes. the margin. A ♀ with broad band on the hindwing is ab. **megasthenes** *Math.* — The butterfly is not rare in New Caledonia and the Loyalty Islands.

macleayanus. **P. macleayanus** *Leach* (42 a, b). Body beneath grey-white, above dark with grey-white hairs, with the exception of the head and the anterior part of the thorax, which are greenish brown-black; legs green; underside of the antenna brown-yellow. Wings above black, a large basal area white-green, on the forewing a spot in the apex of the cell and a second distally to it green, a row of small submarginal spots and a small discal spot white-green. On the under surface the anterior part of the basal area of the forewing, the cell-spot and subcostal spot and on the hindwing the basal area green, without scales, the forewing at the distal margin black-brown, the distal area of the hindwing of the same colour, traversed by a white-grey or pale brownish submarginal band and a short, oblique band of the same colour which is placed behind the apex of the cell, the costal margin of the hindwing narrowly red, especially at the base and before the apex. The young larva is almost black, with white dorsal line and whitish underside, a black hairy tubercle on the 3 thoracic segments and the last segment, the other segments with a transverse row of forked bristles, similar bristles also on the thorax. When full-grown green, with small, faint white and greenish spots and slight dark thoracic belt; on the 3rd segment a pair of dark brown spines, from which extends a yellowish white longitudinal line. Pupa green, with 2 roundish reddish spots on the dorsum; the thoracic horn long. Food-plants: Geijera salicifolia and the imported Camphora officinalis. The butterfly flies in the gardens and open shrubby woods of East Australia from Tasmania to Queensland (extending northwards to about Cairns) and occurs also on the islands Lord Howe and Norfolk. It has a swift and agile flight and is fond of visiting flowers.

weiskei. **P. weiskei** *Ribbe.* ♂: body above brown-black, beneath grey-brown. Wings more elongate than in *P. macleayanus*, the forewing with large subbasal purple area behind the cell, the transverse area at the apex of the cell anteriorly green, posteriorly blue or purple-red, the subcostal spot green, the submarginal spots small and bluish green; the hindwing with green basal area and 2 blue submarginal patches, before which there are usually 3 small, more or less indistinct submarginal spots. Under surface similar to that of *P. macleayanus*; the basal half of the cell of the forewing green, the area placed below the cell white; hindwing with thin red costal streak before the apex. The purple area varies from purple-red to purple-blue. The ♀ similar to the ♂: ♀-f. **weiskei** *Ribbe* (42 a); or the basal area of the forewing and the submarginal spots of the hind-

euprasina. wing green: ♀-f. **euprasina** *form. nov.* — The butterfly is not rare in the mountains of British New Guinea; A. S. Meek found it in considerable numbers at both the south and north sides of the Owen Stanley Range.

P. empedocles *F.* (42 c). Body white-grey, head and upperside of the thorax greenish grey-brown. *empedocles.* Upper surface of the wings greenish black-brown; forewing between cell and hindmargin yellowish grey, with a discal row of yellow-green patches, of which the last is placed between the median veins and is the largest, sometimes there is a smaller patch behind the 2nd median vein, rarely the 1st and 3rd spots are absent; hindwing from the base to about the apex of the cell with grey-white hairs, in the darker distal area a row of blackish patches. Under surface grey-brown, paler in the ♀ than in the ♂; the patches of the forewing scaleless as above; the hindwing about halfway between cell and distal margin with a row of dark spots, of which the last two usually bear on the basal side a red or yellow spot, whilst all are distally and the first spot also basally margined with grey. A Malayan species, very nearly allied to *P. codrus*. Nothing is known as to the earlier stages. The butterfly flies in the hills and is only taken singly. — Malay Peninsula, Sumatra, Batu, Java, Banka, Borneo and Palawan.

P. codrus. Body with white-grey hairs, the upperside of the head and thorax green. Upper surface of the wings silky black-green in the ♂, somewhat paler and almost entirely without gloss in the ♀; forewing with a macular band extending from the apex to the middle of the hindmargin, which is often incomplete and is above green or yellow and scaleless, beneath green-white and scaled; hindwing elongate-triangular, with broad tail, the base and the abdominal margin to about the apex of the cell grey-white. The under surface blackish brown, distally to the band of the forewing only with light and dark shadows, the hindwing, however, often with triangular costal patch as continuation of the band of the forewing; distinct submarginal spots are absent both above and beneath. Full-grown larva yellowish green, the 3 thoracic segments each with a pale red spine at either side, a similar pair of spines on the last segment, the stigmata blue, on segments 4, 11 and 12 a number of small blue dorsal spots (Kühn). According to Wahnes the larva has in New Guinea a large brown dorsal spot, yellow-edged posteriorly, which extends from the 3rd to the 5th segment, and a smaller brown spot on the 11. segment. „The food-plants are trees with large leaves divided into five lobes". Pupa pale green, slightly bluish or yellowish, head obtuse, rounded, with only very feebly produced angles; thoracic horn sharply pointed, with brown tip, the lateral keel running out into the margin of the wings straight, the small lateral tubercle of the mesothorax pointed, without brown spot. The butterfly has a very swift and straight flight; it mostly flies high in the air among the tops of trees, yet it often darts down with lightning speed to feed at flowers or rotten fruit (with which it can be baited); it is especially often seen at the sea-shore, where it is fond of drinking on damp sand. Distributed from the Philippines and Celebes eastwards to the Solomon Islands; does not occur on the large and small Sunda Islands and in Australia, but may yet be discovered on Cape York, where many New Guinean species occur. — **melanthus** *Fldr.* The *melanthus.* band of the forewing yellowish green, very broad, at the submedian broader than its distance from the distal margin; hindwing with large grey costal spot, which beneath reaches the cell. Philippines, apparently on all the islands. — **taloranus** *subsp. nov.* The band of the forewing pale green, not yellowish, as broad as in *taloranus.* *gilolensis*, the costal margin as strongly curved as in *celebensis*. Under surface of the hindwing grey from the middle of the costal to beyond the apex of the cell, but without grey-white spot. Talaut. — **celebensis** *Wall.* *celebensis.* The band of the forewing yellowish green, somewhat narrower than in *gilolensis*, the costal margin strongly curved. North and South Celebes. — **stiris** *subsp. nov.* The band of the forewing yellow-green, very narrow, the *stiris.* penultimate spot at least twice as long as broad. Shape of the wings as in *celebensis*. Sula Islands: Mangoli. — **gilolensis** *Wall.* The band of the forewing yellow-green, consisting of 9 spots; under surface of the hindwing *gilolensis.* with grey-white costal spot. Northern Moluccas: Halmaheira, Batjan. — **codrus** *Cr.* (42 c). The band of the *codrus.* forewing pale green, its last spot small or entirely absent, sometimes the band very narrow; under surface of the hindwing usually with grey-white costal spot. Southern Moluccas: Buru, Amboina, Saparoea, Ceram. — **toealensis** *Rothsch.* The band of the forewing pale green, broader than in *codrus*, the last spot always present, *toealensis.* the white-grey scaling of the hindwing less extended, the tip of the tail much more broadly white-grey. The under surface very dark, the costal spot of the hindwing small. Key Islands. — **medon** *Fldr.* (= papuensis *medon.* *Wall.*) (42 b). The band of the forewing even broader than in *toealensis*, the submedian usually white-scaled inside the band, the hindwing grey-white to beyond the apex of the cell. The under surface paler than in *toealensis*, the costal spot of the hindwing mostly very large and usually prolonged into a band. New Guinea and the neighbouring islands: Waigeu, Jobi, Mafor, Biak, D'Entrecasteaux Islands, Woodlark, Rossel: also on Aru. — **auratus** *Rothsch.* The band of the forewing yellow, the anterior spots somewhat larger and *auratus.* the posterior 2 smaller than in *medon*, the grey-white area of the hindwing reduceed, not reaching the apex of the cell. The grey-white costal area of the hindwing beneath narrow. St. Gabriel, Admiralty Islands (Webster). In consequence of the hostile attitude of the natives no collector has yet succeeded in making a good collection on the Admiralty Islands. Captain H. C. Webster, who attempted to collect there, could not land at all on the principal island and was obliged to take to flight after 2 days. — **segonax** *Godm. & Salv.* *segonax.* (42 c). The band of the forewing broadly interrupted, spots 6—8 being absent, sometimes the 6th and 8th are indicated by a dot each. Under surface of the hindwing without white-grey costal spot. Bismarck Islands: New Pomerania, New Lauenburg and New Mecklenburg. — **pisidice** *Godm. & Salv.* (= solon *Godm.* *pisidice.* *& Salv.*). The band of the forewing complete, pale green, sometimes yellow (discoloured), narrower than in *medon*, the spots more widely separated, the last but one usually narrow and commonly interrupted; the

hindwing less extended grey-white than in *medon*. The under surface darker, the forewing as in the races from the Philippines, Talaut, Celebes and the Sulla Islands with large grey spot at the apex of the cell and grey band in the middle of the cell, hindwing basally grey, with narrow grey discal band, all these grey markings weakly developed. Solomon Islands, known to me from: Bougainville, Shortland, Choiseul, Maleita, Florida, Guadalcanar. — **christobalus** *subsp. nov.* ♀: paler than *pisidice*, especially on the under surface; the band broader; the white marginal spots of both wings much more extended. Beneath the grey cell-patches of the forewing and the grey discal band of the hindwing more strongly developed, the band of the forewing from the 7th spot twice as broad as in *pisidice*. San Christoval, May 1908 (A. S. Meek), 1 ♀ in the Tring Museum. — **tenebrionis** *Rothsch.* (43 a). The band of the forewing only reaches the 1st median, as the posterior 3 spots are absent; the hindwing is much less extended grey-white than in *pisidice*. In some specimens the forewing has a very small green spot at the proximal side of the 1st patch. New Georgia, Rendova, Vella Lavella; probably on all the islands of this western group of the Solomons.

christobalus.

tenebrionis.

Eurypylus-Group.

The 1st subcostal of the forewing runs into the costal, the 2nd subcostal is free or likewise joins the costal. Body above dark with a light stripe at each side. The wings for the most part black, above with green (or yellowish) markings, which are scaleless. Under surface of the hindwing with red or yellow discal spots from the apex of the cell to the anal angle or at least traces of such spots, and usually one or two red or yellow subbasal spots, which are never absent even when the red discal spots are suppressed. The tail when present short and obtuse. — Some of the species are extraordinarily common. Freshly emerged examples and those killed too soon have the markings whitish or yellowish instead of green; decayed as well as worn specimens are likewise yellowish. Such individuals therefore do not represent aberrations, yet fresh specimens are also taken with yellowish markings. The normally red spots on the under surface of the hindwing are replaced in single individuals by yellow ones, which may happen in all the species.

P. cloanthus. Body black, head and thorax above with grey-greenish hairs, beneath grey, abdomen beneath yellowish white with two black lines, above with yellowish white lateral lines. Wings above black, forewing with two large cell-patches and a broad discal band, which is continued on the hindwing in the form of a triangle, hindwing in addition with 4 submarginal patches, all these markings green, transparent, the bands and patches of the forewing as well as the submarginal spots of the hindwing above scaleless. The dark areas beneath somewhat paler than above; the hindwing with red line at the base and small red linear spots from the end of the cell to the anal angle, only the last spot somewhat larger. The ♀ similar to the ♂. Larva green, beneath bluish, on the 4th segment a laterally projecting yellow transverse band, at each side of the back a yellowish longitudinal line. On Machilus odoratissima. Pupa bright green, with yellow carinae. The butterfly occurs throughout the summer; the spring specimens of North India and China differ from the summer specimens in the enlarged green markings. The butterfly has a very rapid flight and is fond of remaining high up among the tops of trees, round which it flies with a dancing motion. The ♂ drinks on wet sand, keeping the wings closed. From Kashmir to the Shan States, China, Formosa, Sumatra; not yet known from Tonkin, Siam and the Malay Peninsula. — **clymenus** *Leech* (vol. I, 8 c), from Central and West China, certainly occurs also in the mountains of South China. The spring form resembles the North Indian summer form, whilst the summer form of *clymenus* is more extended black. In the Tring Museum there is a single specimen from Formosa, which is distinguished from the spring form of *clymenus* by somewhat broader wings and broader submarginal line on the under surface of the forewing. — **cloanthus** *Westw.* The median vein of the forewing is never entirely black in the green parts of the wing, likewise the two median veins are at most black distally in the grey area. In the smaller spring form, f. vern. **cloanthus** *Westw.*, the green areas are large. In the somewhat larger summer form, which has received the unhappily chosen name of f. aest. **cloanthulus** *Fruhst.*, the wings are more extended black. Distributed from Kashmir to the Shan States. — **sumatrana** *Hag.* (45 b). A strikingly different form. Yellow-green, the dark parts of the under surface purple-brown, dusted with reddish grey. In the mountains of Sumatra, the ♀ rare.

clymenus.

cloanthus.

cloanthulus.

sumatrana.

P. sarpedon. Body above brownish black with brown-grey hairs, beneath for the most part white-grey. Wings above brownish black, with green or green-blue discal band, which is strongly narrowed towards the apex and separated into spots and posteriorly on the hindwing is produced into a point; the costal part of the band on the hindwing white-scaled, as also partly the veins intersecting the band; the cell of the forewing nearly always without markings, but occasionally a row of submarginal spots is present; hindwing triangular, with green or blue submarginal lunules. Under surface paler than upper, the discal band scaled with transparent whitish, hence with slight mother-of-pearl gloss; forewing at least with slight indications of submarginal spots before the hinder angle; hindwing near the base with red transverse bar, which extends from the costal margin to the cell and is separated from the discal band; 5 red discal spots, of which the an-

terior one encircles the apex of the cell. ♀ similar to the ♂, paler and somewhat broader-winged. The yellowish egg is laid singly on the leaves and shoots of the food-plants. The young larva is black or dark green, with numerous spines, of which those on the metathorax are long and bristly; when full-grown green, beneath lighter, with a pair of short spines on each of the 3 thoracic segments and on the last segment; on the metathorax a yellow transverse band and from the metathorax to the anal segment a yellowish stripe above the legs; on Machilus odoratissima, Geijera salicifolia, Litsaea, Alseodaphne, etc., and especially Camphora officinalis, where this tree has been imported. Pupa green, the thoracic horn slenderer, more pointed and straighter than in the allied species, the lateral ridges extending downwards from the horn straight, between this carina and the frontal one a very slight, somewhat curved vertical ridge. The butterfly everywhere in wooded districts, very common both in gardens and woods; it flies about the tops of trees with great rapidity, and the ♂♂ are found in large numbers on wet places on the roads and on sandy river-banks. In the mountains it ascends to about 7000 ft., but is commonest in the lower hills. From China and South Japan to the Solomon Islands in numerous geographical forms. Much less common in the east of its range than in the west. In the northern districts distinctly horodimorphic; the band broader in the spring than in the summer specimens. — In **nipponus** *Fruhst.* (= morius *Fruhst.*) (vol. I, 8 c, described as *sarpedon*), from Japan and the Loo Choo Islands, almost all the veins crossing the band are black above and beneath; the under surface of the forewing posteriorly with distinct grey submarginal line, which is not rarely present also above. In the spring specimens: f. vern. **sarpedonides** *Fruhst.*, the band of the forewing is almost as broad posteriorly as the black distal margin, whilst in the summer specimens, f. aest. **nipponus** *Fruhst.*, it is narrower. — **connectens** *Fruhst.* flies on Formosa; the two last spots of the band of the forewing are distinctly narrower than the preceding spot (which however is sometimes also the case in specimens from Okinawa) and the band of the hindwing is strongly narrowed. — **semifasciatus** *Honr.*, from South-East, Central and West China, has three forms: a broad-banded spring form, a narrow-banded summer form and a second summer form with the band of the hindwing more or less obsolete. The two summer forms fly at the same time and are connected by transitions. — **sarpedon** *L.* (= demophon *Meerb.* nec *Linné*, demophoon *Shaw*, luctatius *Fruhst.*, pagus *Fruhst.*, colus *Fruhst.*) (44 d), distributed from Hainan, Tonkin and North India to the Philippines and Lombok. In the broad-banded specimens the median and submedian veins are more or less white inside the band of the forewing. In the summer specimens of the northern districts, f. aest. **melas** *Fruhst.* (= demophoon *Shaw*) the band is narrower and the veins are black. — From the Andamans and Nicobars *sarpedon* is not known. — **teredon** *Fldr.* (45 a) is distinguished particularly in that the band of the forewing is anteriorly yellowish green and posteriorly bluish green and the hindwing is much more strongly dentate at the 3rd radial than in the preceding forms. South India and Ceylon. Specimens in which the 1st spot in the band of the forewing is absent are ab. **thermodusa** *Swinh.* — **rufofervidus** *Fruhst.*, from Nias, has larger red spots on the under surface of the hindwing than *sarpedon*. — **rufocellularis** *Fruhst.*, from Bawean, has a very narrow median band, the spots of which are all separated; the red spot at the apex of the cell of the hindwing beneath unusually large, the posterior red spots on the other hand small. Not known to me in nature. — **adonarensis** *Rothsch.* The band of the forewing posteriorly broader than the black distal margin, the anterior spots larger than in the preceding races; especially the 2nd and 3rd spots, the hindwing quite as strongly produced as in *teredon*. Sumbawa, Flores, Adonara. — **jugans** *Rothsch.* Small; the band of the forewing as in *adonarensis*, but not quite so broad posteriorly; hindwing as in *sarpedon*, the first (white) submarginal spot well developed. Sumba. — **timorensis** *Rothsch.* Very similar to *adonarensis*, the 3rd spot in the band of the forewing nearer to the cell, and the hindwing even somewhat narrower. Timor, Wetter. These forms from the small Sunda Islands further differ from one another and from *sarp. sarpedon* in the genitalia. — From Timorlaut and the islands between Timor and Timorlaut *P. sarpedon* is not yet known. — **choredon** *Fldr.* (= parsedon *Westw.*) (45 a). Similar to broad-banded specimens of *sarp. sarpedon*, the forewing broader, the submarginal spots of the hindwing larger. New South Wales and Queensland. — **messogis** *Fruhst.* (= temnus *Fruhst.*, corycus *Fruhst.*). Not sharply distinguished from *choredon*; the band of the forewing mostly somewhat narrower and the submarginal spots of the hindwing smaller. Distinguishable from *sarp. sarpedon*, apart from the genitalia, by the more uniformly blue-green band and by the submarginal spots of the hindwing being more distinct beneath. Key, Aru, New Guinea and the neighbouring islands (Waigeu, D'Entrecasteaux Islands, Woodlark, Louisiades, etc.); very common. — **imparilis** *Rothsch.* Upper surface deeper black than in the preceding forms, the under surface likewise darker, especially the disc of the hindwing, the red spots larger than in *choredon* and *messogis*. Bismarck Islands: New Pomerania, New Lauenburg, New Mecklenburg, New Hanover, Nusa. Many specimens have a 2nd spot before the subcostal fork, others bear a spot in the cell; it is noteworthy that the spots are not present in any of the 6 ♀♀ before me. — **impar** *Rothsch.* is nearer to the following than to the preceding subspecies. The 1st spot in the band of the forewing is short, transverse, not oblong, before the subcostal in both sexes there is always a 2nd spot, which is commonly as large as the 2nd spot of the band; the submarginal spots of the hindwing larger on both surfaces than in *imparilis*, also the red spots, especially the subbasal line and the spot at the apex of the cell, are large. New Georgia and the neighbouring islands: Kulambangra, Guizo, Vella Lavella, Rendova. — **isander** *Godm. & Salv.* (44 d) resembles *impar*, but bears on the forewing above and beneath a row of submarginal spots; the last of these spots is above only indicated and commonly the two preceding ones also are not developed. Boug-

nipponus. *sarpedonides.* *connectens.* *semifasciatus.* *sarpedon.* *melas.* *teredon.* *thermodusa.* *rufofervidus.* *rufocellularis.* *adonarensis.* *jugans.* *timorensis.* *choredon.* *messogis.* *imparilis.* *impar.* *isander.*

ainville, Shortland Islands, Choiseul, Isabel, Guadalcanar, Florida. Ribbe described as *P. impar Rothsch.* var.
shortlandica. **shortlandica** an example captured on Fauro (Shortland Islands) which has white instead of green bands and spots. It is probably a specimen of *isander* killed too soon (the colour not fully developed). The pupa figured by Ribbe in Iris X, t. 7, fig. 6, judging from the size and shape, is not that of *isander*, but of *P. codrus pisi-*
anthedon. *dice.* — **anthedon** *Fldr.* (= moluccensis *Wall.*) (45 a). The median band of both wings and the submarginal spots of the hindwing more strongly bluish than in all the preceding races; the submarginal spots large and
aureifer. strongly curved; the red spots of the under surface paler red than normally, sometimes yellow: ab. **aureifer**
halesus. *Fruhst.* (= aurifer *Fruhst.*). South Moluccas: Amboina, Saparoea, Ceram. — **halesus** *Fruhst.* As *anthedon*,
crudus. but the submarginal spots of the hindwing somewhat less strongly angled. Buru. — **crudus** *Rothsch.* The band broader than in *anthedon* and *halesus*, the hindwing shorter, the posterior submarginal spots again somewhat less curved than in *halesus*; the under surface of the hindwing with large red spots, a spot between cell and subcostal as in *dodingensis*, *milon*, *monticolus* and *sulaensis*, the red subbasal line broader than
dodingensis. the black streak separating it from the median band. Obi. — **dodingensis** *Rothsch.* The band narrower than in *anthedon*, the 1st submarginal spot of the hindwing almost straight, the next likewise less curved than in *anthedon*; the under surface of the hindwing with deeper red spots, a similar spot between cell and subcostal.
monticolus. North Moluccas: Halmaheira, Batjan. — **monticolus** *Fruhst.* (45 a). A small mountain form from South Celebes (dwarfed form?), which recalls the forms from the large and small Sunda Islands by the green colour of the band and the small green submarginal spots of the hindwing, but agrees better with *dodingensis* and *milon* in the markings of the hindwing beneath and the genitalia. The 3rd spot in the band of the forewing larger than the 4th, which is also the case in the races from the Lesser Sunda Islands; the underside of the hindwing
milon. in both sexes with a red spot between cell and subcostal. — **milon** *Fldr.* (= miletus *Wall.*) (45 b). A large, narrow-winged form with narrow blue band and strongly curved blue submarginal spots; the patches of the band are all separated. Under surface of the hindwing with a broadly concave red spot between cell and sub-
milonides. costal, which is sometimes completed into a ring and occasionally is only a bar. In ab. **milonides** *Honr.* the
citricinctus. band of the hindwing is broadly interrupted at the subcostal vein. ab. **citricinctus** *Fruhst.* has yellow instead
sulaensis. of red spots. The whole of Celebes; Talaut. — **sulaensis** *Lathy* (= coelius *Fruhst.*, adjacentus *Fruhst.*). Similar to *milon*, but the band still narrower. Sula Islands: Mangoli.

P. mendana. Body above black, with light lateral longitudinal stripe, which is greenish grey on the thorax and yellowish grey on the abdomen; sides of the frons yellow-grey. Wings above velvety black; forewing with a discal row of large pale bluish green spots, of which the last is unites with a narrow green subbasal band, at the base a green band, some small spots in the cell and a row of small submarginal spots pale green; hindwing parallel to the abdominal margin with a band which is green in the ♂, white in the ♀, at the distal side of this band between costal margin and cell two patches, some very small submarginal spots white or greenish, often absent, tail obtuse, triangular. Under surface black-brown, spots of the forewing as above, almost all smaller, scaled, a transverse band in the cell and the anterior part of the disc with purple-white scaling, costal margin red at the base; hindwing with a red spot before the cell, commonly a second be-
acous. tween subcostal and cell, and one or two before the anal angle. Solomon Islands. — **acous** *Ribbe.* The discal spots of the forewing all well developed; under surface of the hindwing with green basal spot and two red
mendana. spots before the anal angle. Bougainville; A. S. Meek found the butterfly in January and May. — **mendana** *Godm. & Salv.* (43 a). On the upper surface of the hindwing the green patches of the ♂ and the white area of the ♀ are more strongly developed than in *acous*. The green basal spot on the underside of the hindwing is absent or small and before the anal angle there is only one red spot. Guadalcanar; taken by Meek in
neyra. May. — **neyra** *Rothsch.* The discal spots of the forewing are strongly reduced with the exception of the anterior ones and the last and the posterior ones are absent on the under surface. The forewing beneath without green basal patch and with only one red spot before the anal angle. New Georgia and Rendova.

P. doson. Body above black with bluish grey hairs, abdomen with white lateral line, under surface white. Wings above white with green or greyish white markings, which are scaleless for the most part, on the forewing 5 cell-spots, of which the basal one is streak-like and the 4th comma-shaped, a posteriorly widened discal macular band, a row of submarginal spots and a single spot in the subcostal fork between the submarginal and discal spots; on the hindwing before the middle an elongate-triangular band, which is anteriorly divided by a short, narrow black band, and a row of submarginal spots; the patch of yellow scent-wool in the fold of the ♂ reaches nearly to the black stripe which is parallel with the abdominal margin. The markings on the under surface are mostly somewhat larger than above, silver-scaled; hindwing always with mostly red, more rarely yellow ornamental markings, namely a spot before the costal in the short black costal band, and a row of spots from the apex of the cell to the abdominal margin, of which the last is usually produced basad into a long stripe, the short black costal band never united with the black subbasal stripe. The ♀ similar to the ♂, less deep black and the markings somewhat smaller. Larva black or green, the spines of the mesonotum are absent and those of the 3rd pair are reduced to tubercles. On Anonaceae, e. g. Cinnamomum, Polyalthia, etc. The pupa varies in colour according to

its environment; angles of the head distinctly projecting, thoracic horn bent forwards, gradually pointed, the tip itself rounded, the carinae of the horn sharp and straight. The butterfly in wooded districts, especially near river-beds, in most districts very common; the ♂♂ in abundance in moist places on the roads and river-banks in company with other butterflies; throughout the summer. In North India and Indo-China distinctly horodimorphic; the spring specimens smaller, with larger light markings than those of the summer. Distributed from South Japan and Ceylon southwards and eastwards to the Sunda Islands. The butterfly was first figured by ESPER, as „*jason* LINNÉ sp. 38". As LINNÉ'S *jason* is not this species, there is an error in determination[1]), and FELDER was justified in giving the species a new name: *doson Fldr.* The type of this name is ESPER'S figure. — **doson** *Fldr.* (= telephus *Fldr.*) (43 c). Both wings elongate, the marginal tooth at the 3rd radial of the hindwing longer than the other marginal teeth, the median band of both wings narrow, the subbasal costal stripe of the hindwing above indistinct, not united with the median band, the latter interrupted by a black vein-streak at the hindmargin of the cell. Ceylon. — **eleius** *Fruhst.* differs from *doson* in having the green spots in the apical half of the forewing somewhat more yellowish; mostly also the median band is somewhat broader. South India. — In South Japan flies *mikado Leech* (see vol. I, 8 c). — **perillus** *Fruhst.* Larger than the following subspecies, the submarginal spots of the under surface smaller, the „basal red border is absent, the transcellular black spots are more distinct, but the red ones narrower and paler". Ishigaki-sima. Not known to me in natura. — **postianus** *Fruhst.* (= jostianus *Fruhst.*). Varies considerably in size as well as in the width of the bands; in all examples the median veins of the forewing broadly black and the hindmargin of the cell of the forewing likewise black; summer specimens similar to the following subspecies, but the submarginal spots on the under surface larger. Formosa. — **axion** *Fldr.* (= eurypylus, *Hbn.* nec *L.*, actor *Fruhst.*) (43 c, also as doson U, 32 c aberr.). The spring form, f. vern. **acheron** *Moore* (= nivepictus *Fruhst.*, nivepicta *Fruhst.*, nanus *Fruhst.*), is small, the median band of both wings is broad and the submarginal spots of the under surface are large; this form, from hibernated pupae, is most strongly pronounced in the mountain districts of North India. The summer form, f. **praestabilis** *Fruhst.* (43 c, as axion U), which is not at all sharply distinguished from *postianus* from Formosa, has smaller submarginal spots on the under surface and above the submedian of the forewing and the median of the hindwing inside the band are less black. HÜBNER'S figure, to which FELDER gave the name of *axion*, represents a transition between the pronounced small spring form and the large summer form; it agrees best with certain examples from South-East China. The ornamental spots of the hindwing beneath are sometimes yellow instead of red. South-East China, Hainan, Tonkin, Annam, Cochinchina, Siam, Tenasserim, Burma, Assam, Sikkim, Bengal, North-West India. — **evemonides** *Honr.* (= appuleius *Fruhst.*, autronicus *Fruhst.*, vulso *Fruhst.*). The submarginal spots of the under surface as small as in the summer form of the preceding subspecies, the last two patches of the median band of the forewing above not separated by a black vein-streak, the lower median vein not black or only narrowly so. Malay Peninsula, Sumatra, Banka, Java, Natuna, Borneo, Balabac. — **gyndes** *Fruhst.*, from Palawan and the Philippines, has again larger submarginal spots on the under surface and can scarcely be distinguished from *axion*; in specimens from the Philippines, however, which are also somewhat larger than those from Palawan, the genitalia appear to have somewhat longer teeth on the innerside of the anal claspers. — **rubroplaga** *Rothsch.*, from Nias, is distinguished by a very strong development of the red ornamental spots on the underside of the hindwing. — **sankapura** *Fruhst.* (= sankapurus *Fruhst.*). The median band of the forewing is narrower than in *axion*, *evemonides* and *gyndes*, and the veins intersecting it are broadly black, moreover the band of the hindwing is narrower in the cell than in the forms just mentioned and the black cell-spot on the under surface is very large. Bawean. — **eurypylides** *Stgr.* (= euryphylides *Fruhst.*, ampyx *Fruhst.*) (43 b). All the green resp. white patches very strongly reduced, all the spots of the distal band of the forewing separated by black veins; the band of the hindwing narrow, mostly broken up into spots, especially beneath. Lombok, Sumbawa.

doson. *eleius.* *perillus.* *postianus.* *axion.* *acheron.* *praestabilis.* *evemonides.* *gyndes* *rubroplaga.* *sankapura.* *eurypylides.*

P. evemon. Although very similar to *P. eurypylus*, *evemon* is nevertheless an independent species. The scent-wool of the ♂ always forms a narrow stripe hidden in the fold, the upperside of the abdomen is also never dusted with white in large ♂♂, the last submarginal spot of the forewing above is absent or at most weakly indicated and the harpe of the male genitalia is always recognisable by the long and more basally placed ventral process; moreover. in Malayan specimens the red costal spot on the under surface of the hindwing is always absent. The ♀ similar to the ♂. Nothing is known as to the earlier stages. In its habits the butterfly resembles the allied species, together with which it congregates on damp places on the roads and on sandy river-banks or wet stones in the rivers. When such a swarm is disturbed, the butterflies fly up and down in the forest-paths in Indian file, one behind another, like *Catopsilia* (MARTIN). Distributed from Assam and Tonkin to Java and Borneo; possibly occurs also on the Philippines. — **albociliatis** *Fruhst.* (= albociliatus *Fruhst.*). Under surface of the hindwing with red costal spot as in *P. eurypylus*. May be distinguished from the respective *eurypylus*-form from the same

albociliatis.

[1]) In synomymy falsely applied earlier names are to be distinguished from new but preoccupied names, e. g. *Papilio Eques Achivus jason, Esper* (nec *Linné*, err. determ.) and *Papilio striatus Lathy* (nec *Zink.*, preoc.). In the first case I place a comma between the name and the author who committed the error in determination; it should properly be written *jason L., Esper* (err. determ.),

districts by the absence of the last submarginal spot on the under surface of the forewing and the narrow scent-stripe. Spring specimens have a broader median band and beneath larger submarginal spots than summer ones.

orthia. I have *albociliatis* before me from North-East Assam, the Shan States and Tonkin. — **orthia** *subsp. nov.* Similar to the summer specimens of the preceding form, but much smaller; the third discal spot from the front on the upper surface of the forewing is nearly always wanting, the red costal spot on the underside of the hindwing is absent, the submarginal spots of both wings are much larger beneath than above. Malay Peninsula, Penang,

evemon. Sumatra, Banka, Borneo. — **evemon** *Bdv.* (44 b). Median band broader than in *orthia*, the spots in the apical half of the forewing yellowish, the submarginal spots, especially the posterior spots of the forewing, smaller

igneolus. above and beneath and the red ornamental spots of the hindwing larger. Java. — **igneolus** *Fruhst.* Like *orthia*, but the red spots on the underside larger. Nias.

P. eurypylus. So extraordinarily similar to *doson* that in our revision of the Papilios of the Old World with the exception of Africa (1895) we merged the two species together. The study of the genitalia, however, soon set us right. These organs are indeed almost of the same build in *eurypylus*, *doson* and *evemon*, but they always show distinct differences in the details. In the markings *eurypylus* may nearly always be recognised by the short, brown-black costal band of the hindwing beneath, which bears the red costal spot, being united posteriorly with the brown-black subbasal band, whilst in *doson* it terminates inside the silver band. There are, however, also specimens of *eurypylus*, e. g. among the North Indian spring form, in which the bands are not united. In this case the basal margin of the silver band is notched at the subcostal vein. In the large forms the greater part of the abdomen is generally white above. The yellow scent-wool in the fold of the ♂ forms as in *doson* a broad patch, which extends to the black band which is parallel with the abdominal margin. The harpe (on the innerside of the anal claspers) is distally narrower than in *doson* and bears longer processes; as in that species not only individually but also distinctly geographically variable. The larva on Anonaceae; it recalls that of *doson*, is at first black or brown, in the middle stages brown, yellowish, reddish or green, and when full-grown dark green. Pupa likewise as in *doson*. The butterfly has the same habits as *doson*, with which it flies together in India, Indo-China, Malacca and on some of the Sunda Islands. The distribution of the two nearly allied species, *eurypylus* and *doson*, is interesting. Evidently *eurypylus* is a Papuan butterfly which has spread westwards, but has not (or not yet) reached the western districts of the range of *doson*, whilst *doson* is an Indo-Chinese butterfly which

macronius. has extended eastwards as far as Sumbawa and the Philippines. — **macronius** *subsp. nov.* Large, the abdomen for the most part white, the median band of both wings broad, that of the hindwing dusted with white, at the costal and distal margins of the cell not at all or only feebly incised, the submarginal spots above small, the last on the forewing and the first on the hindwing usually only indicated, the two spots placed in the subcostal fork on the under surface of the forewing separated, the red spots of the hindwing entirely or almost entirely without

cheronus. white edging, hence deeper red than in continental specimens. Andamans. — **cheronus** *Fruhst.* The Indo-Chinese

petina. subspecies is strongly horodimorphic. The spring form, f. vern. **petina** *form. nov.* (= acheron, *Fruhst.* nec *Moore*), is small and has a broad median band, moreover the submarginal spots of the under surface are very much enlarged. The summer form, f. aest. **cheronus** *Fruhst.*, is larger, the abdomen is for the most part dusted with white, the median band of both wings is narrower and the submarginal spots of the under surface are less enlarged. In both forms the band of the hindwing is incised at the costal and hindmargins of the cell, the two spots on the under surface of the forewing placed in the subcostal fork are united, in the summer form, however, often separated by a thin brownish streak, and the last submarginal spot on the forewing beneath is always well developed.

mecisteus. Sikkim, Assam, Burma, Tenasserim, Siam, Tonkin, Hainan, probably everywhere in Indo-China. — **mecisteus** *Dist.* About as large a s the spring specimens of the preceding subspecies, the wings less broad, the median band narrower, the submarginal spots somewhat smaller even than in the summer form of *cheronus*, the spots placed in the subcostal fork on the underside of the forewing separated, rarely touching one another, the abdomen above not

gordion. dusted with white. Malay Peninsula, Sumatra, Borneo, Palawan, Java. — **gordion** *Fldr.* (= tagalicus *Fruhst.*) (44a). Abdomen above more or less whitish, the band of the hindwing above white-scaled, hence in and below the cell less green than in *mecisteus* and *cheronus*. Somewhat larger than *mecisteus*, the median band broader. Philippines, perhaps on all the islands, but only known to me from Mindoro and Luzon, according to FRUHSTORFER on Bazilan. —

insularius. **insularius** *Rothsch.* (= lucius *Fruhst.*, sallastius, *Fruhst.* nec *Stgr.*). Much paler green than the preceding forms, the band of the forewing narrower, the last two patches always contiguous, the antipenultimate more regularly rounded towards the cell than in *mecisteus*; the ornamental spots of the under surface commonly yellow, small, the apex of the cell of the hindwing with silver spot or ring, without red, yet often a small red spot before the apex of the cell. Sometimes the band of the hindwing and the submarginal spots on the under surface strongly enlarged and the short brown costal band of the hindwing entirely separated from the brown subbasal band (as in

sallastinus. *doson*). Kalao and Djampea. — **sallastinus** *Fruhst.* (= gabinus *Fruhst.*). Like the preceding subspecies in the pale colouring, the median band of both wings even more reduced, its spots usually all separated, the two last patches occasionally united, the submarginal spots on the upper surface larger than in *insularius*. Sumbawa,

aloricus. Sumba, Flores. — **aloricus** *Fruhst.* Not known to me in nature. According to the author essentially larger and

lighter green than *sallastinus* and *sallastius*. Alor. — **sallastius** *Stgr.* (43 b), from Wetter. The specimens before me are distinguished by a strongly reduced median band, the spots of which are separated also on the hindwing above and beneath. As in *sallastinus* the cell of the hindwing bears above at the apex an often distinct white spot. — **crispus** *Fruhst.*, from Babber, is unknown to me. According to the description the median band is narrower than in *sallastinus* and broader than in *insularius*, which is incomprehensible, as *insularius* has a broader band than *sallastinus*. — **lepidus** *Fruhst.*, from Tenimber, recalls small specimens from Australia. The three posterior patches in the band of the forewing are connected, rarely the last spot but two is separated, the band of the hindwing is less incised than in broad-banded specimens of *sallastinus*. — **lycaon** *Fldr.* (43 c). Abdomen white-dusted; the median band of both wings very broad, at the hindmargin of the forewing much broader than its distance from the base, on the hindwing white-scaled, sometimes filling up almost the whole of the cell, the submarginal spots also small, but beneath usually large (dry-season form?). Queensland, New South Wales. — **lycaonides** *Rothsch.* (= priscus *Fruhst.*). Larger than *lycaon*, beneath darker black-brown, the submarginal spots smaller. Specimens with yellow instead of red ornamental spots are ab. **aurifer** *Fruhst.* The whole of New Guinea, Fergusson, Waigeu, Jobi. — **extensus** *Rothsch.* differs from *lycaonides* in the larger cell-spots of the forewing, in having the band of the hindwing narrower especially towards the costa and hence straighter, and in the larger red spots of the hindwing beneath. Bismarck Islands: New Pomerania, New Lauenburg, New Mecklenburg, New Hanover. Far less common than the *eurypylus*-forms of the more westerly districts. — **melampus** *Rothsch.* A connecting link between *lycaonides* from New Guinea and *eurypylus* from the Moluccas. Forewing somewhat narrower, the 2nd cell-spot is absent, usually the 1st is also suppressed, the 3rd is very small, beneath the spots are greenish and brownish, reduced, the median band is narrower than in *lycaonides*, the submargianl spots of the upper and under surface smaller than in *lycaonides* and *eurypylus*, the red spot as large as in *eurypylus*, the black spots placed at their proximal side contrast strongly with the brown distal margin and are large. Key Islands, rare. In a specimen in the Tring Museum the red costal spot is enlarged to a short band reaching to the cell: ab. **rufinus** *Rothsch.* — **eurypylus** *L.* (= crocospilus *Röb.*, discoloured specimens) (43 b). Very similar to *melampus*, on the under surface the cell-spot and the posterior submarginal dots of the forewing and the submarginal spots of the hindwing larger. South Moluccas: Goram, Ceram, Amboina, Buru. — **lutorius** *Fruhst.* (= georgius *Fruhst.*). The submarginal spots of the under surface in most specimens larger than in *eurypylus*. Obi, Batjan, Ternate, Halmaheira. — **sangira** *Oberth.*, from Sangir, 1 ♂ in coll. Oberthür. Small, the median band very narrow, on both wings completely broken up into spots, these spots are smaller than in *sallastius*; the ornamental spots of the hindwing beneath yellow instead of red (individual character?). — **pamphylus** *Fldr.* (= telephus *Wall.*) (44 a). Large, costal margin of the forewing strongly curved, the cell-spots as in *sangira* small, but sharply developed, the median band of both wings narrow, the two last patches in that of the forewing almost always connected, the band of the hindwing not at all or very narrowly interrupted, the submarginal spots above and beneath small. The whole of Celebes. — **arctofasciatus** *Lathy* (= sulanus *Fruhst.*) (44 a). Not constantly different from *pamphylus*, the median band still somewhat narrower. Sulla Islands: Mangoli.

sallastius. *crispus.* *lepidus.* *lycaon.* *lycaonides.* *aurifer.* *extensus.* *melampus.* *rufinus.* *eurypylus.* *lutorius.* *sangira.* *pamphylus.* *arctofasciatus.*

P. procles *Grose-Smith* (44 b). Similar to *doson*, the median band very broad, the spots in the apical half of the forewing yellowish, the cell of the forewing without dot in the upper angle or with only a very small one; the hindwing beneath with yellow discal spots from the apex of the cell to the abdominal margin, without yellow or red costal spot, the short brown-black costal band is completely isolated and does not usually extend to the cell. No scent-wool in the abdominal fold of the hindwing. The ♀ very similar to the ♂. The earlier stages unknown. — A mountain species of North Borneo: Kina Balu.

procles.

P. meyeri *Hopff.* (44 a, b). Similar to *eurypylus pamphylus*; the genitalia very different from those of the allied species. Large, abdomen in the ♂ for the most part white, costal margin of the forewing strongly curved, the four linear cell-spots sharply developed, placed more transversely than in *eurypylus*, *doson*, *bathycles*, etc., the 1st continued to the posterior spot of the discal band, and the 4th more strongly curved than in *pamphylus*; the black-brown band bearing the red costal spot of the hindwing beneath is continued distad along the anterior margin of the cell, unites with the dark apical spot of the cell and completely separates the shorter distal costal part of the median band from the proximal longer part. Earlier stages unknown. The butterfly flies in company with *eurypylus pamphylus* and other Swallowtails, especially near water; common. — Celebes.

meyeri.

P. bathycles. Body above black, with ash-grey hairs at the sides of the head and thorax, beneath grey-white, abdomen laterally with a grey-white stripe. Upper surface of the wings black, with pale green markings: on the forewing 5 spots in the cell, a posteriorly much widened discal band, a row of submarginal spots, and a single spot in the subcostal fork at the proximal side of the submarginal spot; on the hindwing 2 large white costal patches, an oblong spot between subcostal and cell, a long spot in the cell and one between the two median veins, often a streak below the cell, a discal spot (often absent) before the 1st median, and a row of submarginal spots. Beneath the spots silver-white, at the base of the hindwing often yellowish, the cell-spots of the forewing and the submarginal spots of the hindwing larger than above, on the hindwing the brownish black costal margin

of the cell is prolonged to the costal margin in the form of a narrow, curved band, inside this band before the costal mostly a yellow spot, in addition a row of yellow spots on the disc from the apex of the cell to the anal angle. No yellowish wool in the scent-fold of the ♂. The ♀ similar to the ♂. The earlier stages not known. In wooded districts of the lowlands and hills, the ♂♂ often in large numbers at wayside puddles and on sandy river-banks. In the northern part of its range the summer specimens are larger and have smaller patches than the
clanis. spring specimens. — **clanis** *subsp. nov.* The cell-spots of the forewing and the submarginal spots of both wings above and beneath fully as large as in the North Indian spring form; the discal spots of the forewing narrow and long and the black vein-stripes separating them as broad as in the North Indian summer form, the cell-patch of the hindwing longer and narrower than in the latter. No light streak at the abdominal side of the hindwing above
chiron. and only a very narrow one beneath. Fokien, one ♂ taken in April. — **chiron** *Wall.* The hindwing bears at least
ligyra. beneath always a white stripe behind the cell. In the spring form, f. vern. **ligyra** *form. nov.*, the discal spots and beneath also the submarginal ones are large, the median veins of the forewing narrowly black, the hindwing with a small discal spot before the 1st median. The summer form, f. aest. **chiron** *Wall.* (= chironides *Honr.*), is larger and the light patches are smaller. Distributed from Nepal to Tonkin, Annam and the Shan
bathycloides. States. — **bathycloides** *Honr.* (44 c). Wings narrower than in the preceding forms: hindwing always without stripe at the abdominal side of the cell, above without discal dot before the 1st median and on the
bathycles. under surface without yellow costal spot. Malay Peninsula, Penang, Sumatra, Borneo, Palawan. — **bathycles** *Zink.* (44 c). Hindwing without stripe at the abdominal side of the cell, above with discal dot before the 1st median and beneath with yellow costal spot; the veins between the posterior discal patches of the forewing and the patches of the basal half of the hindwing above and beneath more narrowly black than in the other forms. Java.

leechi. **P. leechi** *Rothsch.* Distinguished from *P. bathycles* chiefly by the strongly developed woolly scent-organ in the fold of the hindwing. — Chang-Yang, Central China, is sure to occur also further south: only 1 ♂ known.

P. macfarlanei. Similar to *P. eurypylus* and *agamemnon*. Patches on the upper surface scaleless, except the white-scaled costal patches of the hindwing, pale grey-green, in the basal area yellow-green. Forewing with grey basal and subbasal band, the latter nearly always united posteriorly with the discal band, in addition three pairs of spots in the cell and a single spot at its apex, on the disc a band composed of spots, which is strongly widened posteriorly, between this row of spots and the apex of the cell two single spots, further a submarginal row of small spots; on the hindwing an anteriorly broad, posteriorly pointed band before the middle, the band is forked anteriorly and has between cell and subcostal a spur-like projection, which is often isolated and sometimes entirely absent, a curved row of 4 discal spots, which are sometimes reduced to 3 or 2, and a row of 5 or 6 submarginal spots, the marginal tooth at the lower radial only projects a little more than the other marginal teeth. The patches of the underside as above, but scaled with the exception of the spots in the basal part of the cell of the forewing; hindwing in the fork of the light band with a red double spot extending from the costal margin to the cell, another red spot between subcostal and cell and often also one before the anal angle. The ♀ very similar to the ♂, but the light markings of the hindwing often reduced. Larva larger than that of *P. agamemnon*, the thoracic spines smaller, between these spines a longitudinal stripe consisting of dark granules. Pupa with truncate head, the angles of which project distinctly; the thoracic horn laterally compressed (as in *P. agamemnon*), brown, this colour continued as an irregular band from the upper margin of the wing-cases to the apical margin of the 4th abdominal segment, at the sides of the mesothorax a brown spot, which is larger than in *P. agamemnon*. Dr. Hagen found the larva abundantly in New Guinea on the imported Anona muricata. The butterfly is very common in some parts of its range. On the Moluccas, New Guinea with the small neighbournig islands and on
cestius. the Bismarck Islands. — **cestius** *Fruhst.* (= aegistus *Cr.* nec aegisthus *L.*) (45 c ♀, as macfarlanei ♀). The cell-spots of the forewing large, commonly united together in pairs, especially often the two discal posterior cell-spots are confluent; the proximal costal part of the band of the hindwing narrow, sometimes separated from the band, the part of the band placed in and behind the cell narrow, especially in the ♀, beneath the band does not extend beyond the cell, which in the ♀ is often the case above also; the discal and submarginal spots of the hindwing above small, sometimes only 2 or 3 small discal spots are present, moreover the streak- or hook-spot placed between cell and subcostal is always separated from the band at least by the narrowly black veins. Southern Moluccas: Amboina, Ceram, Buru. Originally described from a specimen
macfarlanei. without locality which had become yellowish through discoloration (probably after death). — **macfarlanei** *Btlr.* (45 c). The cell-spots of the forewing mealler than in *cestius*, the band of the hindwing broader and longer, beneath extending beyond the cell, the narrow part of the band placed behind the cell above in the ♀ separated from the large cell-patch at most by a very narrow black vein-streak. Northern Moluccas,
seminigra. Waigeu, Salawatti, Misol, Aru, Jobi, New Guinea (in the Dutch, German and British parts). — **seminigra**

Btlr. (= aegistiades *Honr.*). The upper surface of the hindwing almost entirely without markings. New Pomerania.

P. agamemnon. Body above brown-black, with a green-grey longitudinal stripe at each side; under surface grey. Upper surface of the wings brownish black, with grey or blue-green patches, of which those placed towards the base are band-like and those below the cell of the forewing large and elliptical or almost circular; hindwing with tail, which is longer in the ♀ than in the ♂ and in the Indo-Malayan forms longer than in the Papuan. Under surface paler than upper, the green patches partly covered with white or brownish scales, both wings clouded with violet-grey; hindwing between costal and cell with black crescent, which is basally margined with red, beneath this spot usually a distinct second arc, there is often also a red anal spot and in some forms a row of red discal spots; the red spots are occasionally replaced by yellow. The young larva almost black, with a large light area on the middle of the back, the 3 thoracic segments and the anal segment each with a pair of processes with forked hairs, the other segments likewise with some forked hairs arranged in longitudinal rows; these hairs disappear later; the full-grown larva either ochre-yellow with greenish tinge or dark green, larvae bred indoors sometimes light yellow (want of light? PIEPERS); the thoracic segments each with a pair of black spines, the spines of the 3rd pair in a small orange-yellow spot (in contrast to *sarpedon* there is no yellow transverse stripe on the metathorax); the anal spines light with dark tips. The larva remains by day motionless on the midrib of a leaf. It lives especially on Anona, but also feeds on other trees of the order Anonaceae, e. g. Saccopetalum, Gualteria, Polyalthia, Michelia, and prefers young trees or bushes. The thoracic horn of the pupa is laterally compressed, obtuse when viewed from the side, bent forwards and about twice as long as broad, the tip and the lateral carina brown, the latter undulate; behind the stigma of the prothorax a short brown ridge. The butterfly is very common near the settlements, but also occurs in large numbers in the woods, in the plains and hills; it is fond of visiting the flowers of Lantana. The ♀♀ are especially captured when ovipositing; collections from the Papuan region, where the butterfly is much less common than in the Indo-Malayan districts, and hence is more sought after by the collector, usually contain as many ♀♀ as ♂♂, whilst from India and the large Sunda Islands almost exclusively ♂♂ are obtained. — **agamemnon** *L.* (= dorylas *Sulz.*, rufescens *Oberth.*) (45 d). The spots of the upper surface yellow-green, the three discal patches placed between the lower angle of the cell and the lower median on the forewing broader than the interspaces between them. Specimens with very short stumpy tail are ab. **aegisthus** *L.* (= anoura *Oberth.*). Distributed from South China and North India to Bali and the Philippines. — **menides** *Fruhst.*, from Ceylon and South India, has a longer tail. — **andamana** *Lathy*, from the Andamans, resembles *agamemnon*, but the patches of the upper surface are more grey-green. — **decoratus** *Rothsch.*, from the Nicobars, agrees above with *andamana*, but bears on the underside of the hindwing at least 5, mostly 7 light red spots. — **rufoplenus** *Fruhst.* resembles *ag. agamemnon*, but the red spots on the under surface of the hindwing are somewhat larger. Nias. — **atropictus** *Fruhst.*, from Engano; „a strikingly dark local race; very rare, only 2 specimens". Not known to me in nature. — On Batu flies *ag. agamemnon.* — **baweana** *Hagen* (= aelius *Fruhst.*). The patches of both wings smaller than in the preceding forms. Bawean. — **meton** *Fruhst.* is very similar to *baweana*, but the tail is somewhat longer. The patches in the apical half of the forewing are grey-green. Lombok, Sumbawa, Sumba, Timor? — **exilis** *Rothsch.* (= pedius *Fruhst.*, perecopus *Fruhst.*) (45 d). A small form with small grey-green (slightly bluish) spots. Wetter, Dammer, Babber, Kisser, Tenimber. — **enoplus** *subsp. nov.* Similar to the preceding subspecies, the patches of the forewing still smaller, with the exception of the basal and subbasal bands, which are as broad as in *ag. agamemnon*. The markings of the hindwing are fully as large as in *ag. agamemnon*. Beneath all the discal spots of the forewing are scaled, hence whitish. Palau (= Pelew). — **comodus** *Fruhst.* (= celebensis *Fickert* nec *Wall.*). Large, costal margin of the forewing strongly curved, the patches small. Celebes, Sangir, Sulla Islands, Saleyer, Kalao, Djampea. — **guttatus** *Rothsch.* (= kineas *Fruhst.*, appius *Fruhst.*). The wings broad, the tail very short. The patches of both wings of about the same size as in *comodus*, all well developed; the under surface of the hindwing anteriorly and posteriorly with 2 red patches, which are sometimes very large. The discal spots of the hindwing beneath fully scaled. Northern Moluccas: Morty, Halmaheira, Ternate, Batjan and Obi. — **plisthenes** *Fldr.* (46 a). The cell-spots and the discal ones of the forewing are larger than in *guttatus* and on the whole more yellowish green, commonly the cell-spots are joined together in pairs; the spots of the hindwing more or less strongly reduced. The discal spots on the underside of the forewing partly scaleless (and hence green); the under surface of the hindwing anteriorly and posteriorly with 2 red spots. Hindwing longer than in *guttatus*, in the ♀ with longer tail. Southern Moluccas: Buru, Amboina, Ceram, Goram Laut. — **argynnus** *Drucc* (46 b). Similar to *plisthenes*, but the spots of the hindwing still more reduced, the posterior and distal spots usually absent; both wings narrower. Key Islands. — **ligatus** *Rothsch.* (= atreus *Fruhst.*) (45 d). With broader wings than *ag. agamemnon*, to which this Papaun race is most similar, the tail shorter, the discal patches of the forewing larger, the two discal spots placed between the lower median and the submedian always merged together into a band. The black spots placed at the proximal side of the submarginal spots on the hindwing beneath larger than in *ag. agamemnon*. Distinguishable from *argynnus* and *plisthenes* by the larger spots on the upper surface of the hindwing and the smaller spots of the underside, also at most 3 red spots are present. The whole of New Guinea with the neighbouring islands: Aru, Misol, Waigeu, Jobi, Mafor, Ron, D'Entrecasteaux Islands, Woodlark, Yanarba. — **mynion** *Fruhst.* The tail on the whole somewhat longer than in *ligatus*. Queensland. —

agamemnon. *aegisthus.* *menides.* *andamana.* *decoratus.* *rufoplenus.* *atropictus.* *baweana.* *meton.* *exilis.* *enoplus.* *comodus.* *guttatus.* *plisthenes.* *argynnus.* *ligatus.* *mynion.*

obliteratus. **obliteratus** *Lathy.* Very similar to *argynnus* from Key; the hindwing broader, with shorter tail and beneath with only three red spots, the one placed between the two median veins in *argynnus* being absent in *obliteratus.*

salomonis. Louisiades: St. Aignan, Sudest, Rossel. — **salomonis** *Rothsch.* The patches of the forewing on the whole even larger than in *ligatus*, the submarginal spots however usually smaller; hindwing shorter than in *ligatus*, the submarginal spots and in the ♀ also the discal spots much smaller, some of them absent in the ♀. The under surface of the hindwing always with at least 4 red spots, commonly there is a small red costal spot before the red subcostal lunule. Solomon Islands: Bougainville, Shortlands Islands, Choiseul, Isabel, Guadalcanar, Flo-

ugiensis. rida, Gela, New Georgia, Kulambangra, Rendova, Guizo, Vella Lavella. — **ugiensis** *subsp. nov.* The subbasal stripes and the discal spots strongly enlarged, the three discal spots placed between the 2nd radial and 2nd median on the forewing cut off almost straight distally and the black veins separating them narrow. The under surface of

neopommeranius. the hindwing without red spot between the median veins. Ugi. — **neopommeranius** *Honr.* (46 b). A very striking form. The patches of the forewing small, bluish green; the hindwing almost entirely black. The discal patches of the forewing beneath whitish, scaled. Bismarck Islands: distributed from New Pomerania to New Hanover.

meeki. **P. meeki** *Rothsch.* (49 b). ♀: similar to *P. agamemnon*, hindwing more rounded. Forewing more uniformly spotted (see figure); hindwing with a row of large pale green wedge-patches on the disc, two white spots behind the costal, a green streak in the cell and a green spot before it. The patches on the underside as above, somewhat larger, white; the hindwing with indistinct red lunule between cell and costal vein. — Ysabel (= Isabel), Solomon Islands, one ♀ in the Tring Museum.

P. arycles. Smaller than *P. agamemnon*, tailless. Body as in that species. Wings above with pale green patches, which often fade to yellowish (after death); on the forewing an indistinct basal band, a subbasal band, three transverse spots and a smaller apical spot in the cell, a discal row of patches, of which the 1st and 3rd are small, and a submarginal row of small spots, moreover in the subcostal spot a further isolated discal spot, the last submarginal spot double, but the anterior part placed straight before the posterior part, not as in *P. agamemnon* removed towards the disc, only 2 spots before the subcostal fork; on the hindwing a tripartite subbasal band parallel with the abdominal margin, a discal row of 4 spots, of which the 1st is large and white, and a submarginal row of 6 spots. The patches beneath almost as above, but all with silvery scaling; on the hindwing in addition a small spot at the costal between the subbasal band and the large costal discal spot and also three spots between the 3rd radial and the anal angle red, rarely yellow. The ♀ similar to the ♂. The earlier stages not known. Dis-

arycleoides. tributed from the Shan States and Siam to Java and Palawan. — **arycleoides** *Fruhst.*, from Muok-Lek in Siam, was erected from *one* specimen and differentiated from *arycles arycles* especially by the patches on the upper surface being *always* (!) blue-green and small and the white spot at the costal margin of the hindwing circular

aryeles. and very small. Not known to me in nature. — **arycles** *Bdv.* (= rama *Fldr.*) (45 c, d) shows in its wide area of distribution no tendency towards the formation of further local races. Specimens from localities as far apart as Banka, Palawan and the Shan States are quite similar. The large central costal spot of the hindwing is always somewhat longer than broad. Shan States, Malay Peninsula, Sumatra, Java, Banka, Borneo, Palawan. —

sphinx. Fruhstorfer describes in addition a specimen without locality as *P. arycles* **sphinx**. It is somewhat larger than *arycles* and has narrower spots in the cell of the forewing, and the red spots on the under surface of the hindwing of *arycles* are here replaced by yellow ones. According to the original description the patches of the upper surface are lighter green than in *arycles*, in a later paper, however, they are described as blue-green. A second example,

incertus. likewise without locality, was called by Fruhstorfer *P. arycles* ab. **incertus;** the length of the forewing is 57 mm, which is probably a mistake for 37 mm, and the silver patches in the „median part of the hindwing" are more extended.

Wallacei-Group.

The 1st and 2nd subcostal vein of the forewing running into the costal. Head large. Hindwing rounded, with red subbasal patch on the under surface.

The three species which belong here are nearly allied. But the difference in the genitalia proves that we are dealing with species which have become independent.

P. wallacei. Body above black-brown, head and thorax with grey-green hairs, under surface grey-white, the legs green, the club of the antenna with a yellow spot. Upper surface of the forewing brownish black, with grey-brown silky gloss, at the hinder angle deeper black, a streak in the base of the cell green, some small spots in the cell, a discal macular band, a row of submarginal spots and some further small spots between cell and apex greenish grey, scaleless; hindwing from the base to the apex of the cell grey-brown, this area distally emarginate, the rest of the wing velvety black, before the middle a short band which is green in the cell, and before the apex usually two small greenish grey submarginal spots. Under surface paler brown, shaded with glossy grey, the hindwing near the base with short, green costal band separated from the submedian band by

a narrow black band which bears a red streak extending from the costal margin to the cell, in the apex of the cell a grey ring or half ring, similar spots, filled up with black, on the disc. The ♀ paler than the ♂. The larva similar to that of *P. agamemnon*, on Anona muricata. The butterfly not rare. — **rubrosignatus** *Rothsch.* The middle discal spots of the forewing beneath not scaled towards the cell, the under surface of the hindwing with red spot before the abdominal margin. Northern Moluccas: Batjan, Halmaheira, Obi. — **wallacei** *Hew.* (46 b). The discal patches of the forewing beneath fully scaled, the underside of the hindwing without red spot before the abdominal margin. Aru, Waigeu and the whole of New Guinea. *rubrosignatus.* *wallacei.*

P. browni *Godm. & Salv.* (46 c). The discal band of the hindwing narrow and linear before the hindmargin, the green costal patch on the under surface of the hindwing divided in the middle, with red spot before the costal vein, the part of the green patch placed in the cell is very small or entirely absent, two red spots between the apex of the cell and abdominal margin. — New Pomerania, New Lauenburg, New Mecklenburg, Nussa, New Hanover. In the woods, where the butterflies fly round the tops of trees. *browni.*

P. hicetaon *Math.* The discal band of the forewing broader than in *browni*, but narrower than in *wallacei*; upper surface of the hindwing entirely or almost entirely without costal spot, beneath the red costal streak reaches to the cell, distally to this streak there is either no green spot or only a very small one, on the other hand at its proximal side there is invariably a large green double spot, which always only extends to the cell. — Solomon Islands, known from Bougainville, Shortlands Islands, Choiseul, Florida, Guadalcanar, Ugi, Rendova, Vella Lavella, Guizo. *hicetaon.*

Macareus-Group.

The 1st subcostal of the forewing runs into the costal. Ground-colour of the wings pure white or with greenish tinge, the veins black-striped, the interspaces with light longitudinal stripes as in *Danaus*, sometimes, however, almost all the light markings or also the vein-stripes suppressed (mimics of Euploeas). The under surface of the hindwing without red or yellow ornamental spots, except that an anal spot is often present; the hindwing rounded, with the exception of *P. phidias*, which is tailed.

These mimetic species must evidently be derived from tailed forms which were allied to *P. aristeus* and *P. antiphates*. Concerning the earlier stages nothing in known. The butterflies are inhabitants of the woods and have quite the sluggish flight of the Danaids. The species were formerly erroneously placed near *P. clytia*. They may be grouped as follows:

A. Tailed: **P. phidias.**

B. Tailless:

1. Abdomen with black median line on the underside: **P. macareus, xenocles, leucothöe, delesserti.**
2. Abdomen without black median line on the underside, the cell of the hindwing very narrow: **P. megarus, megaera, stratocles, deucalion, thule.**
3. Abdomen without black median line on the underside, the cell of the hindwing broad at the point of origin of the subcostal vein, the light parts of the wing also above all scaled: **P. idaeoides, encelades.**

A. Phidias-Subgroup.

Tailed. Only one species known.

P. phidias *Oberth.* One of the most interesting butterfly discoveries of recent times, the species being a precursor of the tailless mimetic forms. Wings black with the following white marks: on the forewing five cell-bands placed almost perpendicularly to the hindmargin of the cell, below the cell a broad band divided into longitudinal patches by the black veins, which is continued costad from the 3rd radial by two rows of small spots; between this band and the distal margin a row of linear longitudinal spots, two in each marginal cell; hindwing from the base to the apex of the cell white, with black stripes as in *P. eurous*, distal part of the wing brown-black with small light submarginal spots, double yellow anal spot and before this some small yellow spots; tail narrow, about as long as the distance from the apex of the cell to the distal margin. — Annam. Three ♂♂ in coll. Oberthür. *phidias.*

B. Macareus-Subgroup.

Tailless.

P. macareus. Abdomen with black median line on the underside. The scent-organ of the ♂ strongly developed. Wings above black or brownish black with white or greenish white markings. ♂: cell of the forewing with 3 stripes, which are sometimes broken up into small spots, and 2 apical spots, outside the apex of the cell a row of 4 dots, distally to these 4 spots, between the 2nd radial and the hindmargin 5 stripes, of which the 3rd and 4th (separated by the submedian fold) are sometimes completely confluent; hindwing from the base striped with white, the cell entirely or for the most part white, with black transverse line before the apex, on both wings a row of submarginal spots. Under surface brownish, the light markings in the distal third of the hindwing mostly less distinct than above. The ♀ in some districts similar to the ♂, in others much darker. Sometimes there

is in the ♂ a small yellow anal spot on the hindwing. The butterfly is common in most districts. The ♂♂ congregate in swarms at wet places, whilst the ♀♀ are taken singly in the woods on flowers, on which they rest with the wings closed. Distributed from North India to Hainan, Bali and the Philippines. The dark ♀♀ resemble

indicus. Euploeas. — **indicus** *Rothsch.* (= polynices *Nicév.*) (46 c). ♂: all the white stripes broad, the three stripes in the cell of the forewing complete, the cell of the hindwing entirely white, the oblique subapical line weakly developed. ♀: very similar to the ♂, the white discal stripes of the forewing broader than the black vein-stripes

lioneli. separating them. Sikkim. — **lioneli** *Fruhst.* (32 d, ♀). ♂: either exactly like *indicus* or the light stripes somewhat narrower. ♀: forewing brown-black, with white submarginal spots, the light discal stripes scarcely indicated; hindwing with white spot in the apex of the cell and white stripes round the cell, these stripes narrower than in *indicus*, the posterior ones not extending to the base, the submarginal spots well developed. Assam. In one of the ♂♂ in the Tring Museum, from the Khasia Hills, the submarginal spots of the hindwing above and beneath are enlarged, beneath they form a band which commences behind the subcostal with a specially strongly enlarged

gyndes. spot, the costal margin is broadly edged with brown. — **gyndes** *subsp. nov.* The ♂ as in *lioneli*, the white stripes mostly somewhat narrower than in *indicus*. The ♀ (name-type) similar to the Sikkim ♀, but the white spots in the apical half of the forewing and the distal half of the hindwing smaller. Burma. — The ♂♂ from Tenasserim have narrower white stripes than in the preceding forms, but the cell of the hindwing is still almost entirely filled up with white, moreover the 3 cell-stripes on the upperside of the forewing are not or not distinctly interrupted.

indochinensis. The specimens form a transition to the next form. — **indochinensis** *Fruhst.* (= striatus *Lathy* nec *Zink.*). ♂: the 2nd and 3rd cell-stripe of the forewing also above broken up into spots, the white cell-stripe of the hindwing narrower than the brown-black border of the cell, the discal stripes of both wings thin. ♀: both wings for the most part brown-black as in the ♀ of *lioneli*, the light discal spots much more reduced than even in that form, on the other hand the submarginal spots of the hindwing larger. Specimens of both sexes also occur in which the light discal stripes of the hindwing are widened and some of them at least connected with the large submarginal spots: ab.

argentiferus. **argentiferus** *Fruhst.* (♀ = serda *Fruhst.*). This aberration flies singly among normal *indochinensis*. Siam, Annam,

mitis. Tonkin. — **mitis** *subsp. nov.* ♂: the light stripes above as strongly reduced as in *indochinensis*; beneath the 4 anterior discal spots of the forewing are small and diffuse and the costal margin of the hindwing is less grey than

perakensis. in the preceding races. Hainan. — **perakensis** *Fruhst.* has the white markings almost as large as in *indicus*, but the costal margin of the hindwing beneath is brown. In a ♂ from Perak in the Tring Museum the submarginal

xanthosoma. spots of the hindwing are confluent with the discal stripes. The ♀ of *perakensis* is unknown. — **xanthosoma** *Stgr.* Abdomen yellow-brown instead of black, rarely brown-black, the under surface with two white lines, between which is placed a black line. The light stripes of both wings narrow. The ♀ similar to the ♂. East and West

macaristus. Sumatra. — **macaristus** *Grose-Smith* (47 b). Body black with 4 white lines as in the continental forms. The light stripes of the wings narrow, at least one of the anterior discal spots of the forewing united into a stripe with the corresponding dot placed distally to the apex of the cell; the discal stripes of the hindwing very thin, especially beneath; the costal margin of the hindwing beneath without light stripe. ♀ similar to the ♂. North

maccabaeus. and South Borneo. — **maccabaeus** *Stgr.* The light stripes of the forewing almost as broad as in *indicus*, the anterior discal spots oblong, usually united with the dots placed distally to the apex of the cell; the stripes of the hindwing likewise broader than in *macaristus*, the discal spots placed at the apex of the cell short and beneath shaded with

macareus. brown, the submarginal spots small. The ♀ unknown. Palawan. — **macareus** *Godt.* (= striatus *Zink.*) (46 c, d). ♂: the light stripes on the forewing broader than in *indicus*, on the other band the stripes and spots of the hindwing smaller, the costal margin of the hindwing beneath without light stripe. ♂♂ in which the discal stripes of the

palanus. *masformis.* hindwing are united with the submarginal spots are **palanus** *Fruhst.* The ♀ in two forms: ♀-f. **masformis** *Lathy*

astina. is similar to the ♂, but has narrower white stripes, and ♀-f. **astina** *Westw.* is for the most part brown. The Tring Museum possesses an example of ♀-f. *masformis* from Sukabumi; the specimen described by Lathy (in coll. H. J.

albinovanus. Adams) came from Java. — **albinovanus** *Fruhst.*, from Bali, is said to have even larger light stripes than *macareus*. Described from a ♂. Unknown to me in nature.

P. xenocles. Very nearly allied to *P. macareus*, mostly considerably larger, the wings broader, the light stripes larger than in the respective *macareus*-races from the same districts, the hindwing always with yellow anal spot, which in dark ♀♀ is sometimes only indicated. Distributed from North India to Hainan and Siam. The butterfly occurs at the same localities as *P. macareus*, in company with which it is met with; it is rather rare in the eastern districts of its range, on the other hand common in Burma, Assam and Sikkim. According to Fruhstorfer the dry-season (spring) examples have the distal border of the hindwing beneath lighter brown

phrontis. and broader than those of the wet season (summer). — **phrontis** *Nicév.* ♂: the white discal and cell-stripes broad. ♀ similar to the ♂, the discal stripes of the hindwing somewhat narrower; in a ♀ in the Tring Museum, from Sikkim, in addition the spots placed in the cell and in the apical half of the forewing are smaller than in the ♂. The specimens (♂♀) in which the distal margin of the hindwing beneath is narrow and

xenocrates. black-brown are according to Fruhstorfer the rainy-season form: f. aest. **xenocrates** *Fruhst.* Sikkim and Bhutan.

xenocles. — **xenocles** *Dbl.* (47 a). The ♂♂ as the preceding; the ♀ on the other hand much darker, the light stripes being very strongly reduced; the forewing usually lighter brown basally than distally, the cell-spots thin and

towards the costa indistinct or suppressed here, the light discal stripes much narrower than the dark vein-stripes; the yellow anal spot of the hindwing always small, often only just indicated. The ♂♂ from Assam with light brown marginal area on the under surface of the hindwing are f. vern. **theronus** *Fruhst.*; I cannot distinguish them from specimens from Sikkim. — **kephisos** *Fruhst.* ♂: the light discal stripes of the hindwing on the whole somewhat narrower than in the preceding forms. The ♀ similar to the ♂, but the light stripes narrower; the only ♀ known to me is distinguished from *phrontis* by the narrower light markings. The ♂♂ with broader and lighter brown distal margin to the hindwing beneath are according to FRUHSTORFER the dry-season form (= spring form): f. vern. **neronus** *Fruhst.* Burma, Tenasserim, Shan States, Tonkin. — **lindos** *Fruhst.*, of which only a few ♂♂ are known, has rounder wings, very broad white stripes and small yellow anal spot. Siam. — **xenoclides** *Fruhst.*, from Hainan, has narrower light stripes than all the other forms. *theronus.* *kephisos.* *neronus.* *lindos.* *xenoclides.*

P. leucothoë. Differs from *P. macareus* and *P. xenocles* chiefly in the shorter and more rounded hindwing, which has no yellow anal spot, in the reduction from the basal side of the light patches and the longer discal stripes of the hindwing. Even in the lightest specimens the cell-spots of the forewing are not developed costally; none of the light stripes of the hindwing nor the posterior stripes of the forewing quite reach the base, whilst the discal stripes of the hindwing are very broad and extend close to the submarginal spots; in the darkest specimens only the submarginal spots of both wings and the short discal stripes on the hindwing are developed. The ♀ has even less and smaller light markings than the ♂. Malayan. The butterfly, which is Euploeid-like in appearance and flight, flies in the spring and autumn in wooded districts of the plains and hills. — **leucothoë** *Westw.* (47 b). ♂: the posterior white stripes of the forewing usually reach the cell, and the cell of the hindwing is for the most part white, moreover the cell of the forewing has mostly a number of white spots. ♀: forewing brown, with small submarginal spots, and before the hindmargin a trace of a discal streak; on the hindwing, in addition to the submarginal spots, there are 6 brown-shaded grey discal stripes, which are more distinct on the underside, moreover the cell bears beneath a small apical spot, which above is only indicated. Malay Peninsula and North-East Sumatra. Some specimens not distinguishable from the next form. — **interjectus** *Honr.*, from South-East and West Sumatra, has no spots in the cell of the forewing, the discal stripes of the forewing are short, the anterior discal spots usually dot-like, and the cell of the hindwing for the most part black-brown. In the ♀ the discal stripes of the hindwing are somewhat smaller than in the ♀ of *leucothoë*. — **ramaceus** *Westw.* (47 b). A much darkened form. ♂: the discal stripes of the forewing are suppressed, at most there are traces of two spots before the hindmargin. The discal stripes of the hindwing are short and always much narrower than in the preceding forms, usually much narrower than the interspaces. ♀ without discal spot on either wing; the submarginal spots small, partly suppressed, beneath somewhat larger and here there are also faint discal stripes before the abdominal margin of the hindwing. North and South Borneo. *leucothoë.* *interjectus.* *ramaceus.*

P. delesserti. Body above black, at the sides of the thorax with greenish grey hairs, head spotted with white, underside of the body white, abdomen with black median and lateral lines. ♂: wings white, very slightly greenish, with black vein-stripes which are widened at the distal margin, the white stripes of the forewing enclose a submarginal row of black patches, the cell of the forewing for the most part black, with white spots and lines; hindwing with yellow anal spot, before which a second spot is usually placed, both spots beneath large. The black markings on the under surface smaller than above. The ♀ larger than the ♂, the black markings reduced, the light parts of the wings transparent, smoky or chalky white, the yellow anal spot small. The earlier stages unknown. The butterfly flies in wooded districts in the plains and in the hills and occurs all the year round, but is especially common in the spring. Whilst the ♀♀ are only rarely captured, the ♂♂ are met with in large numbers on sandy places on the river-banks and at wayside puddles. The ♀ is a strikingly faithful copy of the Danaid *Ideopsis daos* and the Zygaenid *Cyclosia pieridoides*. Malay Peninsula to Java and Palawan; on Java the butterfly has not been found again recently. — **delesserti** *Guér.* (= laodocus *Deh.*, dehaani *Wall.*, catoris *Grose-Smith*, labienus *Fruhst.*, sacerdotalis *Fruhst.*) (47 c). The three short white discal streaks near the apex of the cell on the hindwing above are narrower in the ♂ than the black vein-stripes between them. Malay Peninsula, Penang, Sumatra, Banka, Java, Borneo, Natuna. — **hyalinus** *Fruhst.* The costal margin of the forewing beneath somewhat more extended black at the apex in both sexes than in the preceding form, and the white submarginal spots on the upperside of the hindwing straighter in the ♂. Nias. — **palawanus** *Stgr.* (= palawanicus *Rothsch.*). The three white discal stripes which are placed near the apex of the cell on the upper surface of the hindwing are broader than in the preceding forms, the white cell-patches on the forewing beneath are intersected by black longitudinal lines, which seldom occurs in the other forms. Palawan. *delesserti.* *hyalinus.* *palawanus.*

P. megarus. Underside of the abdomen without black median lines. The scent-organ of the ♂ strongly developed. The white markings slightly greenish; forewing with 3 rows of greenish white spots between cell and distal margin, the spots of the two inner rows placed between the 1st median and the submedian united into three stripes, on the other hand the spots placed before the 1st median nearly always isolated; on the hindwing in the basal half some long greenish white stripes, round the apex of the cell several short streaks and between these and the distal margin three rows of spots, of which the submarginal ones are lunular. The

light markings vary individually in size. The ♂♂ common on moist sand, the ♀ singly in the woods. — In
megarus. **megarus** *Westw.* (= loki *Röb.*) (46 e), from Assam, the cell-spots of the forewing are small above and almost
similis. entirely absent beneath. Its occurrence in Sikkim is doubtful. — **similis** *Lathy* (= meagrus *Fruhst.*, megapenthes *Fruhst.*, mendicus *Fruhst.*, martinus *Fruhst.*). The cell-spots of the forewing well developed also be-
sagittiger. neath. Hainan, Tonkin, Siam, Shan States, Tenasserim, Malay Peninsula, North-East Sumatra. — **sagittiger** *Fruhst.* The light stripes thinner and the spots, especially the submarginal ones, smaller than in the preced-
fleximacula. ing forms, the cell-spots of the forewing present also beneath. North Borneo. — **fleximacula** *Rothsch.* Forewing with white stripe instead of 2 spots before the 1st median; submarginal spots small. Banguey Island, a pair in coll. STAUDINGER.

megaera. **P. megaera** *Stgr.* (46 e). ♂ and ♀ paler brown than *megarus*, the light markings in the basal half of both wings absent above and beneath, or very faintly indicated on the upper surface of the hindwing. Palawan.

P. stratocles. The light markings purer white than in *megaera* and *megarus* and with the exception of the submarginal spots larger; the forewing bears between the hindmargin and the 2nd radial or even the subcostal fork white discal stripes; the cell of the hindwing is entirely white or has only traces of two black lines.
stratocles. The light markings in the ♀ larger than in the ♂. Palawan, Mindoro, Mindanao. — **stratocles** *Fldr.* (= magicus *Stgr.*, stratoclides *Lathy*) (47 d). The cell-spots of the forewing and the discal stripes of both wings broad. Palawan, Mindoro. FELDER originally gave Mindanao as locality, but the ♂ described by him came from Min-
stratonices. doro. — **stratonices** *subspec. nov.* ♂: the white stripes much less strongly developed, the cell-patches of the forewing obsolete towards the costa, the discal stripes of the hindwing partly shaded with brown, the submarginal spots, especially on the hindwing, smaller than in *stratocles*. ♀: the white markings almost as much reduced as in the ♂, or at least the submarginal spots of the hindwing above and beneath smaller than in the ♀ of the preceding form. Mindanao.

P. deucalion. Similar to *stratocles*, mostly larger, the cell-spots of the forewing broken up into dots, the light stripes of both wings shorter, the cell of the hindwing before the apex with black oblique line, on the disc of the hindwing a row of 4 or 5 small spots. In the ♀ the white markings somewhat larger than in
deucalion. the ♂. Celebes and North Moluccas. — **deucalion** *Bdv.* (47 d). The light markings yellow. North and South
leucadion. Celebes. — **leucadion** *Stgr.* (47 d). The light markings white, slightly yellowish, smaller than in *deucalion*, partly shaded with black, the stripes of the forewing, however, somewhat longer. North Moluccas: Halmaheira, Batjan.

P. thule. Nearly allied to the preceding species; very variable, in all specimens the light markings are white, with slightly greenish tinge (the wing-membrane of the light spots, beneath the scales, greenish), which is often absent in the light ♀♀. Forewing without light stripe at the hindmargin or this stripe in light ♀♀ feebly developed; on the hindwing the light stripes united into a central area, which is distant from the base or extends to near the same only below the cell, being usually very strongly reduced from the basal side; the veins which intersect this area are mostly very narrowly black; the cell of the hindwing bears no black oblique line as in *deucalion*. In dark specimens the light markings of the body are also reduced. There do
fumosa. not appear to be any fairly constant geographical differences. The principal individual forms are: f. **fumosa** *form. nov.*, the area of the hindwing above reduced, intersected by rather broad black veins, beneath so densely scaled with brown that the light spots are barely indicated; several ♂♂ in the Tring Museum from the
leuthe. hills of British New Guinea; on the rivers running into Redscar Bay. f. **leuthe** *Grose-Smith* (32 b), the discal stripes of the forewing short, cell of the forewing without markings or the cell-spots small, the area of the hindwing far removed from the base; Waigeu and north side of Dutch and German New Guinea, less pronounced
thule. dark specimens also in the southern parts of New Guinea. f. **thule** *Wall.* (= alfredi *Fruhst.*), some at least of the stripes of the forewing extending to the cell, narrower than the black vein-stripes, the area of the hindwing moreover does not reach the base posteriorly, the cell-spots of the forewing distinct; in the entire geo-
goldiei. graphical range of the species. f. **goldiei** *Godm. & Salv.* (= princeps *Weym.*) (32 c). The light stripes of the forewing broader than in the preceding form, usually broader than the black vein-stripes separating them, the area of the hindwing nearly reaches the base posteriorly; in the ♀ the light stripes are especially strongly developed, also the cell-spots of the forewing are large and sometimes the posterior half of the cell is occupied by a long, uninterrupted patch; apparently as widely distributed as f. *thule*. All these forms are connected by transitions. — The species is hitherto only known from Waigeu and various parts of New Guinea, but probably also occurs on Aru and the islands off the coast of New Guinea. The butterfly in the woods; the different varieties are mimics of Danaids.

idaeoides. **P. idaeoides** *Hew.* An extremely noteworthy mimetic butterfly on account of its great similarity to its model (*Hestia leuconoë*). In the markings similar to *P. delesserti*; the cell of the hindwing much broader, the scales normal. Wings white with black markings as may be seen from the figure; the under surface resembles the upper. The ♀ is marked exactly like the ♂, somewhat larger. — Only known from Mindanao.

P. encelades *Hew.* (49 b). Cell of the hindwing broad. Forewing elongate, with incurved distal margin; white, at the costal and distal margins black, the black distal area anteriorly extended to the apex of the cell; hindwing white with broad black distal margin. Under surface almost as upper, the dark parts paler, the light areas intersected by dark veins, cell of the hindwing with dark longitudinal streak, both wings with grey-white submarginal spots, which above are mostly only weakly indicated. The ♀ does not appear to be known. — North and South Celebes. *encelades.*

2. Genus: **Eurycus** *Bdv.*

An Aristolochia butterfly, which in many respects approaches *P. polydorus*. Differs from *Papilio* chiefly in the shorter, thicker, not curved club of the antenna, the much larger basal cell (so-called precostal cell), and in having the precostal vein curved towards the base. The ♀ has after copulation a „pouch" like the ♀♀ of *Parnassius* and of the South American genus *Euryades*. Legs as in the Indo-Australian Aristolochia-Papilios distinguished from those of the Aristolochia-Papilios of America by the deeper apical incision of the 5th tarsal joint. Larva not yet described; we have been told by R. E. Turner that it is similar to that of *P. polydorus*; on Aristolochia. Pupa with girth; similar to that of the Aristolochia-Papilios, but much more cylindrical, the wing-cases not expanding and the dorsal humps of the abdomen small and almost coniform; head truncate; with a horn at each side above and beneath; grey-yellow, striped and marbled with brown-yellow. — One Papuan species.

E. cressida. ♂ and ♀ similar in shape, different in colouring. ♂ black, frons yellowish white, thorax and abdomen marked with red. Forewing transparent, this part only scaled above, the margins dark, the base black; cell long, with black spot opposite the base of the upper median, a second black spot on the discocellulars. Hindwing black, distally strongly rounded, abdominal margin even more slightly bent over than in *polydorus*, incurved behind the middle, a median band consisting of white patches extends from the costal to the distal margin; a row of submarginal spots red, more or less densely dusted with black, at the distal margin light spots. Underside as above, but the submarginal and marginal spots of the hindwing more distinct. ♀ much paler than the ♂, both wings for the most part transparent, yellowish smoke-colour; the light scales at the base of the forewing form thin undulate lines; the discocellular spots smaller than in the ♂, the cell-spot replaced by an indistinct transverse patch, hindwing either transparent with indistinct markings, or similar to that of the ♂, but the dark parts paler, the submarginal spots yellowish grey, beneath more or less distinctly reddish. The pouch towards the front with 2 lateral flaps and 3 central processes placed one over another. Both sexes vary considerably in size. The butterfly is common; it has a straight and rather feeble flight, but hastens away with great rapidity when it is frightened. It visits flowering trees and sometimes swarms in numbers round flowering Eucalyptus. — **cressida** *F.* (= heliconides *Swains.*, ♀ = harmonia *F.*, harmonides *Godt.*) (49 c). Under surface of the hindwing with distinct marginal spots. In northern Australia, Thursday Island (perhaps also on the neighbouring islands), and on the small islands between Timor and Timor-laut, which perhaps it has only recently reached: Sermatta, Babber, Letti, Moa, Kisser. One of the ♂♂ before me from Moa has yellow instead of red submarginal spots on both sides of the hindwing. — **troilus** *Btlr.* Hindwing without distinct marginal spots in both sexes; hindwing of the ♀ smoky black, with white median band; British New Guinea. *cressida.* *troilus.*

3. Genus: **Leptocircus** *Swains.*

Head broad, thorax thick, abdomen scarcely longer than the thorax; the antennae extend beyond the apex of the cell of the forewing; above scaled, the fine sensory hairs almost uniformly distributed over the scaleless underside, club short and broad; legs scaled. Neuration: in the forewing subcostals 1 and 2 from the cell, 3 and 4 long-stalked, 5 from this stalk nearer to the cell than to branch 4, anterior angle of the cell pointed; in the hindwing the cell very small.

Forewing triangular, the hindmargin much shorter than the distal margin, before the middle a light oblique band, which is continued on the hindwing and is in part scaleless, between cell and distal margin a large, transparent. scaleless, triangular area, which is divided by thin black vein-stripes into 6—8 spots; hindwing narrow and long, folded, produced into a very long tail, which is distally edged with white. ♂ and ♀ similar; ♀ with large ventral copulation-groove before the tip of the abdomen.

Two species. Most nearly allied to the Kite-Swallowtails, from which *Leptocircus* is without doubt derived. The possession of a scent-organ in the abdominal fold of the hindwing of *L. curius* and of a tooth at each of the tarsal claws in the same species, as well as the powerfully built body, the markings of body and wings, the scaled greenish legs, etc., recall Kite-Swallowtails. We consider it quite a mistake to separate *Leptocircus* from the *Papilioninae* as a distinct subfamily.

Concerning the earlier stages nothing is known, except that the egg is *Papilio*-like. The butterflies are common in most parts of their range. They occur near the water in open places, over which they dart backwards and forwards near the ground. their rapid flight resembling that of dragonflies; they are immoderate water-drinkers, and often squirt the water out again rhythmically at the anus. They are also commonly met with at flowers, before which they hang with the wings vibrating rapidly and the tails quivering and raised high, without resting on the flower.

The genus is distributed from South-East China and Assam to Java, Celebes and the Philippines.

L. curius. Tarsal claw with long tooth; fold at the abdominal margin of the hindwing of the ♂ with white scent-organ; the oblique band of both wings white. North-East China, Assam, south and east to Java
walkeri. and Palawan. Several geographical forms have been erected, which, however, completely intergrade. — **walkeri** *Moore* (49 d). The black median band of the forewing posteriorly narrowed, very often incomplete, the
curius. white band consequently widened. South-East China, Tonkin, Hainan. — **curius** *F.* As the preceding, but the black median band of the forewing broader and always complete. From Assam to Palawan and Java.
libelluloides. — **libelluloides** *Fruhst.* (49 d). The transparent area of the forewing narrower and the veins intersecting it thicker black. Nias.

L. meges. Tarsal claw simple. Hindwing of the ♂ without scent-organ. The oblique band of both wings green (scaleless, the membrane of the wing green). The genitalia likewise easy to distinguish from those of *L. curius.* Distributed further to the east than *curius*, *meges* being represented also on the Philippines and
virescens. Celebes, but does not extend so far north on the continent as *curius.* — **virescens** *Btlr.* The black median band of the forewing never twice as broad in the middle as the green band, in the northern districts usually even somewhat narrower than the latter; the grey scaling at the base of the hindwing beneath rather sharply
meges. defined. Hainan, Tonkin, Burma, Shan States, Annam, Siam, Malacca. — **meges** *Zink.* (49 d). The black median band of the forewing usually half as broad again in the middle as the green band; the grey scaling at the base of the hindwing beneath extended to the first grey transverse line, the white band broader than the
niasicus. black band placed basally to it. Sumatra, Borneo, Java. — **niasicus** *subsp. nov.* The transparent area of the forewing smaller than in the preceding forms, consisting of 7 sections, of which the first is small, the black distal margin as broad as in the form from Celebes, the green band one-third narrower behind the middle than the black band; under surface of the hindwing with very distinct transverse lines before the abdominal
decius. margin, the grey basal area does not reach the transverse angular patch. Nias. — **decius** *Fldr.* (= wilsoni *Reak.*) (49 d). The green band of the forewing narrower than in the preceding forms, about half as broad as the black median band; the grey basal area of the hindwing beneath smaller than in *meg. meges.* Balabac.
ennius. Palawan, Domaran and all the islands of the Philippines. — **ennius** *Fldr.* (= curtius Wall.) (49 d). Larger, especially the hindwing, and the tail strikingly longer; the vitreous area of the forewing narrower, intersected by thick black veins; the green band above and beneath narrow on both wings. Celebes, apparently commoner in the north of the island than in the south.

4. Genus: **Teinopalpus** *Hope.*

Frons projecting conically; palpi very long, pointed, porrect; antenna short, with strong, obtuse, curved club, scaleless except at the base, the segments almost cylindrical, the sensory hairs almost uniformly distributed over the underside. Neuration similar to that of *Papilio*, the median spur of the forewing only indicated, the upper transverse vein of the forewing short, the 2nd long and incurved, apex of the forewing pointed, hindwing with 1 (♂) or 2 (♀) long tails. — The earlier stages not yet described, the larva is said to live on Daphne nipalensis. The butterfly is very local and only occurs at medium and higher elevations on the mountains (6—10,000 ft.) in wooded districts. It usually remains in the tops of trees, from which it only comes down from about 8—11 o'clock in the morning when the sun is shining, and can then be attracted by baiting. Its flight is exceedingly fast. The best localities are open places on the tops of mountains surrounded by timber-forests. One species. Distributed from Nepal to Tenasserim; also in Central China.

T. imperialis. ♂: body green, beneath yellowish. Upper surface of the wings green on black ground; forewing before the middle with black, gently curved line and between it and the distal margin 2 broad, blackish, indistinctly defined shadowy bands, the extreme margin black, the fringes white; hindwing with black median line, at the distal side of which there is a yellow area, and the space from here to the abdominal margin is edged with white, before the distal margin green-yellow submarginal lunules, tip of the tail yellow. Under surface to the black median line green, the rest of the forewing brownish yellow with black bands; the hindwing almost as above. ♀ larger than ♂, paler, above on the forewing with two grey bands, on the hindwing with large grey central area, which is narrower and yellow before the abdominal margin, marginal teeth longer than in the ♂, the tooth of the 1st radial developed into a tail, which is shorter than the tail of

the 3rd radial and at the apex yellowish grey. Under surface: basal area green, rest of the forewing grey with black bands, hindwing almost as above, sometimes entirely without yellow. — **imperialis** *Hope* (= himalaicus *Rothsch.*, ♀ = parryae *Hope*) (49 c). ♂: the yellow area of the hindwing, although very variable in size, always enters the apex of the cell and beneath reaches the 1st median. ♀: the central area of the hindwing above is grey with a little black to the 2nd median and from there onwards yellow, beneath this area is sometimes mostly black and without yellow. Nepal, Sikkim, Bhutan, Assam, Upper Burma. From April to August. The ♀♀ from Sikkim and Bhutan appear to have a paler under surface to the hindwing (*himalaicus*) than ♀♀ from Assam, yet examples also occur in Assam which are as pale as Sikkim specimens or even paler. — **imperatrix** *Nicév.* ♂: less densely scaled with green than the preceding form, the yellow area of the hindwing does not enter the cell and beneath reaches to the 2nd median; marginal teeth longer. ♀: the grey area of the hindwing above anteriorly densely dusted with black, posteriorly broader than in *imperialis*, yellow as far as the 3rd radial and beyond, marginal teeth longer. Upper Tenasserim: Toungoo, January to April; in the Tring Museum 2 ♂♂ and 1 ♀, inclusive of the name-types (♂♀).

imperialis.

imperatrix.

5. Genus: **Armandia** *Blanch.*

This genus differs from *Papilio* principally in having the median spur of the forewing only very weakly indicated. It belongs to the essentially Palaearctic subfamily *Thaidinae* (or *Zerynthiinae*).

Body with rough hairs, weak in proportion to the size of the wings; head small; palpi pointed, projecting; antenna scaleless, thin, short, with weak club, the sensory hairs dense at the base of the segments on the underside; abdomen long, thickest in the posterior half; legs short. Wings long, forewing rounded, the 1st and 2nd subcostal free, the 3rd—5th stalked together, the 1st radial arising near the upper angle of the cell; hindwing long-toothed, with long tail at the 3rd radial and a shorter one at each of the median veins, precostal vein directed basad, basal cell large. — The earlier stages unknown. Two species, in medium to higher elevations on the wooded mountains of North India and West China. The butterfly has a feeble flight, recalling *Hestia* and allows itself to be driven backwards and forwards by the wind between the tops of trees like a dry leaf. It also visits flowers, and during a shower it sits on a leaf and pushes the forewing over the hindwing, so that the brillant colours of the latter are concealed (Doherty). From the spring to September. The sexes similar.

A. lidderdalei. Black with grey lines, as may be seen from the figure. Hindwing from the 2nd radial to the abdominal margin with large bright-coloured area, which is proximally rose-red and distally black and is bordered by yellow patches; on the black part two bluish grey spots, which bear basally a white line or dot; tail obtusely pointed, not spatulate as in the Chinese species *A. thaidina*. Beneath similar to above, the markings larger, the rose-red area paler. The ♀ somewhat larger than the ♂. North India and West China. — **lidderdalei** *Atkins.* (49 c). The cell-lines of the forewing only very slightly curved, the blue-grey spots on the black area of the hindwing large. Bhutan, Naga Hills in North-East Assam, Chin Hills in North-West Burma. — *spinosa Stich.* occurs in West China.

lidderdalei.

6. Genus: **Parnassius** *Latr.*

The genus *Parnassius* is purely Palearctic. We must regard as its original home the Central Asiatic mountains, from whence the species spread in the glacial epoch over the whole of non-tropical and non-arctic Asia and the non-arctic regions of Europe, and there is no doubt that the North American Parnassiids also have found their way across the Alaskan bridge to Alaska and the Rocky Mountains.

It is not improbable that originally all the Parnassiids inhabited the lowlands, and some of the species only ascended into the higher mountains as the continental ice receded. Certain it is, however, that some of the recent species retained the steppe-frequenting habit (abundance of *P. mnemosyne* in the Hungarian Puszta and the steppes on the Volga), whilst the principal contingent belongs to the mountains. The Indian species are exclusively mountain-dwellers and even favour preeminently the high alpine regions, which alone, at this southernmost limit of their occurrence, can offer them the accustomed conditions of existence.

But even this southern migration upwards, which has taken place close to the boundary of the tropics and to the climatic barrier between the high plateaus of Asia and the hot lowlands of India, has produced no essential modifications in the habitus of the genus.

The character of the wing-pattern preserves the same scheme as in the purely Palearctic Region, a constancy which gives to the Parnassiids the exclusive and uniform stamp by which they are so strikingly distinguished from their nearest relatives, the Papilionids, which in India more than elsewhere are subject to essential variations in the contour of the wings and scheme of markings.

But at the same time the southern slopes of the Himalayas and the mountain ranges adjoining them on the north produce those forms which are conspicuous as the most brightly coloured (*hardwicki*) or the most ornamentally marked (*charltonius*) among all the species.

The general characters of the genus are dealt with in detail in the Palearctic part vol. I, p. 19, and in vol. V, p. 45 of the exotic fauna.

We therefore merely point out here that the Parnassiids are morphologically distinguished from the Papilionids by the absence of the transverse vein between median and submedian near the base of the forewing and the hindmarginal vein of the hindwing.

The clasping-organs of the Parnassiids approximate very closely to those of the Papilionids. The uncus is provided with two claw-like points, the valve relatively long, oval and armed with a strongly projecting, distally rather pointed process (the clunicula), which also occurs in *Ornithoptera*. The penis is sword-like, with the apex sharp and curved somewhat outwards.

The most striking pecularity of the Parnassiids is the pouch of the females, the structure of which may serve as a help in determination.

The Indian species also may be divided according to this organ into several heterogeneous groups.

simo. **P. simo** *Gray*, the most insignificant species of the whole region and on the whole the smallest species known as yet, is characterised by a tubular or vermiform pouch. Only four specimens are known to have yet been brought to Europe; these were taken in Ladak, or Chinese Tartary as the district was called at that time, at an elevation of 16,000 ft. The species is weakly coloured, with small, dark-bordered eye-spots on the hindwing. — Kashmir.

acconus. **P. acconus** *Fruhst.* (= moelleri *Bingham*) (50 e). Of somewhat more imposing appearance; with distinct light red ocelli and with continuous submarginal band, which is not broken up into single spots as in *simo. acconus* was discovered before the English-Tibetan war in Kambajong, at the border of Tibet and Sikkim, and is said to have been taken at an elevation of 16,000 ft.

acco. **P. acco** *Gray* (vol. I, 16 c) is distinguished from *simo* by the varnished appearance of the under surface and the larger, deeper red ocelli. Likewise very rare, discovered together with the preceding species in Kash-
gemmifer. mir, also on the Karakorum, where it occurs at an elevation of 17—19,000 ft. — From Kambajong **gemmifer** *Fruhst.* has been described, recognizable by the darker distal margin and the deeper red ocelli of the hindwing with broader black markings. The pouch of *acco* is sack-shaped, enclosing the body with two lobes, and is furrowed beneath.

delphius. **P. delphius** *Ev.* (vol. I, 15 d, e). One of the species with the greatest tendency to geographical dif-
stoliczkanus. ferentiation, it sends off five known branches into the region of the Himalayas. — **stoliczkanus** *Fldr.* (vol. I, 16 c). Hindwing with broad marginal band, on which are situated 4—5 roundish darker spots, which in the ♀ are dusted with blue. Taken at an elevation of 16—18,000 ft. Flight low, rapid, in zigzag, entirely different from that of *hardwicki* and *jacquemonti*, similar to that of *charltonius Moore*. North-Western Hima-
atkinsoni. layas, Kashmir. — **atkinsoni** *Moore* we regard as a brilliant ♀-form, with much broader black longitudinal bands of the forewing and strongly enlarged red patches and ocelli and the hindwing. Pir Pingal, North Kash-
hunza. mir. — **hunza** *Gr.-Grsh.* is somewhat larger than *stoliczkanus*; described from the Hindu Kush, but extending into the Indian territory at Chitral near the border of Afghanistan. The band-markings are somewhat reduced, the disc plentifully dusted with grey. Distal margin of the hindwing much narrowed, the submarginal spots,
stenosemus. however, very well-developed, quadrate. — In **stenosemus** *Honr.* (vol. I, 16 b) a widening of all the black bands is noticeable, which recalls *atkinsoni*, but the submarginal spots of the hindwing are isolated as in *hunza*, with distinct blue centres. Ladak, Kuti Pass, 17,000 ft.

lampidius. **P. lampidius** *Fruhst.* (= whitei *Bingh.*) (50 e). Recognizable by the pure white ground-colour; it is perhaps the smallest known *delphius*-race; from Kambajong, South Tibet. All the black markings reduced, especially also the marginal band and the submarginal spots of the hindwing. The basal area of the hindwing on the other hand more extended black than in the other known forms, recalling *staudingeri Bang.-H.* The ocelli of the hindwing light carmine red, but smaller than in *atkinsoni*. The pouches surround the body in ring-shape, are broader than high and have two points.

jacquemonti. **P. jacquemonti** *Bdv.* (50 b). According to VERITY this species is distinguished by the predominantly melanotic colouring of the ♂♂ in contrast to the other Parnassiids, whilst the ♀♀, usually dark in other species, are here without exception much lighter and almost pure white. The species is extraordinarily inconstant and varies very considerably in size, ground-colour, and the number and shape of the red spots, which, as in the European *apollo*, may be with or without white centres. These differences may perhaps be traced back
impunctata. to seasonal dimorphism. — The least marked form has been described as **impunctata** *Austaut* (50 b), from Sikkim. Kashmir specimens are somewhat smaller in both sexes, invariably more richly adorned with red and mostly with two red preapical spots. Specimens are also known with the forewing still darker than in
himalayensis. the figure and of a vitreous appearance. — I refer the name **himalayensis** *Elw.* (50 c) to the form from the eastern Himalayas, of which I have a number before me from Native Sikkim, distinguished by the pure white ground-colour, the smaller and lighter red ocelli, the narrower vitreous distal margin of the hindwing and the more

sharply defined submarginal spots. — **rhodius** *Honr.*, from Kashmir, differs in the more circular ocelli and the diffuse submarginal bands of the hindwing. — **chitralensis** *Moore* is a local form with pure white ground-colour, reduced black and red spots on the forewing, but more extended black basal spot on the hindwing, which sends tooth-like projections into the middle of the wing, and more reniform red ocelli. Chitral. — *jacquemonti* is a high alpine species, which has been found on the passes of the Himalayas at elevations of 10,000 to even 18,000 ft. The butterflies fly low and rapidly over snow-fields or the frozen ground, even where the least vegetation can no longer exist. Time of flight July to September. The ♀♀ of the races of *jacquemonti* possess keeled pouches, whilst those of the following *epaphus*-series have instead of the keel a pouch with transverse folds at the broad end. *rhodius.* *chitralensis.*

P. epaphus *Oberth.*, from the north-west Himalayas (Ladak), is a species which flies in July and August, has been observed up to a height of 15,000 ft. and is locally common, although it is seldom brought to Europe. Oberthür's type belongs to the rainy-season form, recognisable by larger red ocelli and broader black bands than the form *cachemiriensis Oberth.* (vol. I, 15 c), which has smaller spots and ocelli and pure white instead of ochre-yellow ground-colour. Near Leh, Kashmir, the latter is not rare. — **nirius** *Moore* (vol. I, 15 b), which belongs to *epaphus* on account of the melanotic colouring of the ♀ (which is much darker than the ♂), is a habitually small individual aberration, likewise from Kashmir, and only to be distinguished from *epaphus* by the complete submarginal band of the forewing, not broken up into separate spots (Bingham). *epaphus.* *nirius.*

P. sikkimensis *Elw.* (50 d) is a well-defined, very small local form from Native Sikkim, where it was taken by Elwes in September 1870 on the Tibetan border at an altitude of 19,000 ft. Also in South Tibet (Kambajong) the species is still common, but varies much in size, some specimens even approximating to the North Tibetan *nanchanica Aust.* by their large red ocelli, whilst dark examples also occur with the disc of the forewing densely dusted with black. *sikkimensis.*

P. hardwicki *Gray* (vol. I, 15 b) represents in its most developed forms decidedly the most brightly coloured species of all the Parnassiids, with such a wide range of variation that Moore devoted to it in the Lepidoptera Indica three plates with 24 coloured figures, no two of which are alike, and yet the peculiar moss-green tinted under surface only occurring in *hardwicki* (similar to that of certain *Colias*) is not once represented there. *hardwicki.*

hardwicki was discovered by Major Charlton in Kashmir together with *acco* and *simo*. There and in Simla the species occurs all the year round. It prefers bare mountain peaks only overgrown with grass, flying slowly above the tree-limit like ordinary sluggish Pierids, but can also hasten rapidly over the rocks. Two broods have been definitely proved. Moore even believes there is evidence of the existence of three, but only an early spring and a late autumn brood are certain. The latter apparently hibernates, for Capt. Lang has seen *hardwicki* flying in December and February on fine days which followed on weeks of snow-storms. Young found large numbers of pupae in the middle of October and believes that even more pupae than imagos hibernate. The larvae, like those of the allied species, feed on species of Saxifrage. The species varies least in the western Himalayas, the lighter forms fly at elevations of 7500—9000 ft., the dark ones from 10—15,000 ft. I consider that two races can be differentiated, namely *hardwicki Gray* (vol. I, 15 b), from Kashmir and the western Himalayas with the extremely albinotic development f. **otos** *Fruhst.* (50 c), and **charino** *Elw.* (50 d), the melanotic high alpine form. — For the smaller Sikkim race, which particularly in the female is also dusted with darker green beneath, the name **viridicans** *subsp. nov.* (50 c, d) may be introduced. Of this **afer** *Fruhst.* is a darkened form, **albicans** *Fruhst.* an albinotic one, and **parva** *Verity* an undersized mountain form. The ♀♀ are the most brightly coloured, being always darker than the ♂♂ and also beneath marked with red on a green ground. The pouch is compressed laterally, bladder-shaped, whitish yellow, with a deep longitudinal furrow on the underside. *otos.* *charino.* *viridicans.* *afer.* *albicans.* *parva.*

P. imperator *Oberth.* (50 a, ♂; ♀ vol. I, 16 f) is the largest representative of the group. One of the rare ♂♂, which are found in very few collections, is here figured, and also a race from South Tibet, taken near the border of Sikkim, **augustus** *Fruhst.* (50 b). This highly specialised local form differs from *imperator* in the yellowish, sometimes even canary-yellow ground-colour and the more sharply defined and narrower black bands of both wings, the very large red, transparent basal patch and the red tear-shaped spots (resembling those of *jacquemonti*, *epaphus* and *hardwicki*, but even larger) in the cell and the subanal area of the hindwing. The red ocelli of the hindwing remain smaller, but are more broadly margined with black and as well as the blue anal ocelli have more white in the centre. *augustus* does not equal *imperator* in size, on the other hand the submarginal band of the forewing is almost twice as broad, moreover all the yellowish bands on the forewing show a tendency to increase in width. Pouch of the ♀ similar to that of *delphius*, but stronger, darker, with two pointed lobes. *imperator.* *augustus.*

Among the most conspicuous of all the species is also

P. charltonius *Gray* (50 a), distinguished by the gorgeous, mostly very large, quadrate, light red ocelli and the isolated, large black blue-centred submarginal spots of the hindwing. In contrast to *augustus* there *charltonius.*

are in *charltonius* no red basal spots on the hindwing beneath, instead of these is a blackish area densely covered with yellow scales. Pouch of the ♀ limaciform. Kashmir, North-West Himalayas. — MOORE says that *charltonius* skims over the ground with an irregular, swimming flight, like a pointer following the scent of game. at elevations of 4500—5000 m. The ♂♂ of *charltonius* and *imperator* are always rarer than the ♀♀, which is explained by the fact that the ♂♂ are fond of circling round inaccessible, isolated mountain peaks, and only come down for copulation to the lower alpine meadows, where alone the ♀♀ find conditions suitable for oviposition. It is known of *charltonius* that the ♂♂ dart up and down with great rapidity and can only occasionally be taken, when the sun is covered by clouds or strong, cold winds set in, when the butterflies seek shelter on the rocks. *augustus* and *charltonius* are very local and both show much less tendency to variation than other Parnassiids. Also the seasons appear to exercise no influence on their colouring. In *charltonius*, however, the extent of the red of the ocelli varies somewhat. — Specimens in which the latter are especially
deckerti. richly adorned with red VERITY has named **deckerti.**

Additions and Corrections.

P. 14: **Papilio priamus arruanus** ♂-ab. **chrysopsila** read **chrysophila.**

P. 21: **Papilio helena papuensis.** There are in German New Guinea among the ♂♂ specimens in which
rubra. the hindwing is red instead of golden: ♂-ab. **rubra** *Pagenst.* Not known to me in nature.

P. 22: **Papilio helena bandensis** *Rothsch.* (1908) is **bandensis** *Pagenst.* (1904).

P. 23: **Papilio helena mannus** *Fruhst.*, from Bali, I cannot distinguish from Javan specimens (*P. h. helena*).

P. 33: **P. ikusa** *Ehrm.*, recently described from Simoda, Japan, sinks to *alcinous Klug.*

P. 48: A large series of examples of **P. xuthus,** from Formosa, now before me, confirms my suspicion that **koxinga** *Fruhst.* was founded on a discoloured specimen. The name *koxinga* must therefore be regarded as synonymous with *xuthus.*

P. 57: **capaneus** *Westw.* from Queensland.

P. 61: Line 3 read ♂-f. **depicta** instead of ♀-f.

P. 62: Line 6 et seq. read Savu instead of Suva.

P. 67: ♀-f. **nymphasia** is = ♀-f. **capsus** *Ribbe* (1898).

P. 79: Line 40 read forewing instead of hindwing. (K. Jordan.)

2. Family: **Pieridae, Whites.**

The greater part of the species of this cosmopolitan family live in South America and South Asia. The number of genera in the two regions is about the same.

It is true that sharply defined species are rather more numerous in South America, but the Indian archipelagos produce an astonishing variety of local races, so that the two regions rival one another in a way which makes it difficult to decide where the maximum of development is to be sought.

The large number of forms is due to local and climatic influences. The mightiest expanse of mountains in the world, the Himàlayas with their off-shoots and the lowlands lying before them, are fully as favourable to the formation of species as the numerous islands in the Malay Archipelago. The highly diversified climatic conditions, partly caused by the regularity of the Monsoons and the consequent steady alternation of dry seasons and rainy periods, contribute further to the modification of species.

Hence we meet both in the high-mountain species and in those of the plains and islands with unstable forms, often broken up into polychromatic and even polymorphic elements, the elucidation of which formerly occasioned serious difficulties. These forms have been described in the earlier works as an endless number of species, and to reduce them to their true status and to ascertain their geographical connection will be one of the principal objects of the following pages.

But in spite of this extensive morphological variation all the Pierids have much in common; such as particularly their very similar earlier stages and certain social habits. A noteworthy peculiarity of the Asiatic Pierids is their fondness for water, which is shown in their propensity for congregating on wet places in small or large numbers. They are frequently met with at river-banks or muddy places in such numbers that horses often shy when the Pierids rise up with an audible rustle. Sometimes they group themselves according to species so that the assemblages look like large flowers with white centres and gaily-coloured petals, or suggest large patches of snow, as I frequently observed in Siam. Most striking, however, is the peculiar migratory instinct of the Pierids. *Appias* and *Catopsilia* in particular follow an irresistible impulse and unite in swarms which travel even over mountains of 6000 ft., suspending their flight at sunset to resume it the next day with the same determination. I once observed such a flight in Java. On a sunny day, on the 13. January 1892, enormous swarms of *Catopsilia* began flying over Sukabumi in a westerly direction. These clouds of butterflies presented a wonderful spectacle, the flight lasting from 11 till towards 2 o'clock and the swarms appearing, as far as could be estimated, to be over 2 km. in breadth. The butterflies followed one another sometimes in large crowds, sometimes in groups at distances of from several inches to a few feet and at a height of about 4—6 m above the ground. On the 14. and 17. January similar flights were observed, but of shorter duration. The causes of the migration of such swarms have not yet been satisfactorily explained; the phenomenon observed by me was preceded by an unusually dry year, in which not a drop of rain had fallen in East Java for months, so that the consequent want of food perhaps furnished a motive for the emigration.

Like the imagines the Pierid-larvae also often occur in such abundance as to become injurious, and are especially dangerous to young Ironwood trees (Cassia florida L.). Grass and low bushes in the neighbourhood of these plantations are then covered with the pupae, from which the butterflies emerge in January, in such numbers as to fill the air as if with white snow-flakes (MARTIN).

The eggs of the Indian Pierids are spindle-shaped, being sometimes very wide, so that they look like soda-water bottles, twice as high as broad, with longitudinal ribs, which are connected by fine transverse ridges. Towards the apex they are sometimes produced into a short point. The colour principally white, variable, sometimes becoming yellow and orange. The eggs of *Huphina* are spotted with red and those of *Leptosia* are whitish to quite blue. The eggs are as a rule laid singly on the upperside of a leaf or on young shoots. Exceptions are *Colotis amata F.*, *Appias hippoides Moore*, *Delias eucharis Don.*, *Anaphais mesentina Cr.* and *Terias silhetana Wall.*, whose eggs are deposited in clusters. The larvae of these species live gregariosly in the first stages, but separate when they are well grown if they find sufficient food.

The larvae of the Asiatic species, when adult, lie on the upperside of a leaf and, when they live isolated, along the midrib, where they cover the leaf with a silver web. Some are said to have carniverous tendencies,

eating one another with no apparent cause and in case of want of food even attacking the larvae of other species. It has also been observed that *Appias*-larvae for instance greedily devoured the pupae of *Leptosia* (Bell).

The larvae of some species, such as *Hebomoia glaucippe*, which are ornamented with eye-spots, sometimes assume a terrifying attitude and are said to look like small snakes. On this account, according to Piepers, the Javanese are even afraid of these larvae.

The pupae as a rule have a pointed, sometimes snout-shaped head and are sometimes protectively adapted to their surroundings. When they hang down from leaves they are green, near the cassia flowers yellow, and when fastened on grasses they become black-brown like the grass-seeds or like dried pods (Martin, Piepers). The length of the pupal stage varies somewhat, lasting in *Terias* only 6 days.

In neuration the Pierids stand nearest to the Papilionids, from which, however, they are distinguished by the proportionately larger hindwing. The hindwing is always especially broad, being traversed by a second inner-marginal vein, which is absent in the Papilionids, and moreover is often so widened as to partly envelop the abdomen.

The contour of the wings is mostly rounded, but there occur also long and narrow, as well as sharply pointed and angled forewings and strongly dentate hindwings. Tails, as are frequently found in the Papilionids and many Nymphalids, are, however, entirely absent.

The ground-colour is predominantly white with black transverse stripes, yet we also find red, yellow, orange, bluish, brown, black colours and beneath, though very rarely, even green colouring. But nearly throughout there is a vivid contrast between the mostly unicolorous upper surface and the often very gay under surface. All the markings, however, can easily be traced back to a row of marginal spots and a row of submarginal ones alternating with them, as well as some circumcellular patches (Aurivillius). In the more temperate districts of the subtropical zone, especially if by vertical elevation they are removed a few degrees further back into the colder zone, the components of the fauna still belong to the Palaearctic genera with their primitive and monotonous colouring. The nearer the tropical zone, however, the brighter becomes the colouring, which is charmingly shown even on the small Sunda Islands with their comparatively few species.

In general the Pierids have a long season of flight, and in the commonest species of *Catopsilia, Appias, Pieris, Terias* the successive generations overlap.

The ♂♂, like most butterflies, are throughout sun-loving and gregarious, whilst the ♀♀ prefer the shade of the woods, where they are occupied in seeking suitable food-plants for their offspring. As they travel less, they are never met with at the drinking-places, but appear to be satisfied with a smaller supply of water, which they find for instance on the leaves of the forest-vegetation.

Many Pierids present typical examples of that resemblance to other butterflies which has been named Mimicry. — The origin of this resemblance, however, is now explained by the supposition that the mimics were modified by the same (as yet unknown) influences under which the colouring of the models, mostly Danaids, developed.

On the continent only a few species are localised, as their distinctions are very easily effaced by migration, whilst on the islands the representatives of one and the same species are broken up into a varied series, the forms occurring near to the centre of the range being still very similar to the primitive type, whilst those at the extreme limit can scarcely be recognised as belonging to the same species.

Very interesting zoogeographically is the conflict of two large faunistic regions in the Malay Archipelago, the Oriental and the Australian, which were formerly believed to be separated by Wallace's line of division.

Another interesting phenomenon is that the three large Sunda Islands often produce the same species as the Malay Peninsula — and that both Malacca and Perak have many more species in common with Sumatra and Borneo than with India and Burma — and especially that the Malay forms almost without exception assume the character of insular races. This peculiarity in the fauna goes hand in hand with a similar pecularity in the flora and is repeated in all families of Lepidoptera and in other insects, so that it was desirable to introduce a collective name for this geographical zone. As the expression „large Sunda Islands", hitherto in use, only includes Borneo, Sumatra and Java, and takes no account of the Malay Peninsula, „Macromalayana" was chosen — in contrast to „Micromalayana", for a faunistic region which begins with the island of Bawean, north of Java, and not, as hitherto accepted, with Bali, and embraces all the small Sunda Islands.

The originals for the figures of plates 50—73, with the exception of a very few figures which were taken from specimens in the British Museum, are exclusively from the collection of Fruhstorfer in Genf-Florissant. in which are also contained the types of the new forms and races which are here described for the first time.

Nova Hedf 1924

1. Genus: **Leptosia** *Hbn.*

Small, delicate, white butterflies, irrorated beneath and with the forewing rounded. Antenna long and spindle-shaped with compressed club. Palpi short but hairy, the hairs long anteriorly. Subcostal three-branched, with two branches before the end of the cell. Egg blue; larva similar to that of *Terias hecabe*, but more delicately green and with fine hairs; on Capparis and Crataeva. Pupa green shaded with various colours. The butterflies occur in large numbers. They have a slow but irregular flight, are found at open places in the woods and at their edges in the undergrowth, and are fondest of thorn-bushes.

L. xiphia *F.* (62 f), distributed over the whole of India and Ceylon, also found by me in Siam and Annam. An inhabitant of the plains, but ascends to 7000 ft., and sometimes appears in such crowds that the English in India call it „the wandering snow-flake". The under surface is finely spotted with greenish with traces of two more distinct transverse bands on the forewing. — **nicobarica** *Doh.* is an island race with very narrow black distal margin to the forewing, and otherwise more reduced and paler markings; Nicobars. — **malayana** *subsp. nov.* A somewhat larger subspecies, but nevertheless with smaller subapical spot in the forewing; beneath with two distinctly prominent greenish transverse bands. The larger Sunda Islands and Malay Peninsula, with the exception of Java, where **chlorographa** *Hbn.* (62 f) occurs, with relatively large black dot on the forewing and uniformly yellow-spotted under surface of the hindwing without band. Java, Bali; common in the dry season and ascending to 3000 ft. — **fumigata** *Fruhst.* (62 g) is an unusually large race with broad subapical spot and the under surface of both wings densely dusted with black. The butterfly ascends to 2000 ft. and occurs at the edges of woods by the sea-shore in April-May in a profusion which is often quite bewildering; over and over again I have found them in the net even when I have been in quest of other species. Lombok to Flores. — **aurisparsa** *subsp. nov.* (62 g) is perhaps only a dry-season form of the preceding with gold-yellow scales on the hindwing beneath. Savu Island, August. — **comma** *Fruhst.* (62 f) is a well-marked race in which the tip of the subapical dot is constantly united with the apical margin of the forewing. Islands of the Timor Group, Key, Timor-Laut. — **aebutia** *subsp. nov.* is a form with the subapical spot of the forewing as large as in *fumigata*, but sprinkled with light yellow beneath. Tana-Djampea, Kalao; flies in December. — **dione** *Wall.*, a distinct local form, as large as *fumigata*, but without a trace of a black apical margin on the forewing, with a roundish subapical patch placed much more proximally and yellowish-scaled under surface. Hitherto only observed in the immediate neighbourhood of Macassar. South Celebes. — **terentia** *subsp. nov.* is likewise somewhat deficient in black markings, also beneath very pale; the apical spot of the forewing only reaches to the upper radial, but is sharply defined. South Philippines, Bazilan, February, March; Mindanao. — **georgi** *subsp. nov.* The reverse of the preceding, with broad, diffuse black markings; the apical margin of the forewing reaches to the middle of the wing; but under surface pale, almost without green-yellow scaling. North Philippines, Luzon; flies in August, November. — **niobe** *Wall.* The most northerly race known, similar to *terentia*, but the very deep black apical margin to the forewing bearing but indistinct grey scaling; the transverse bands on the hindwing beneath distinct. Very common in Formosa, where it ascends to 4000 ft.

xiphia. *nicobarica.* *malayana.* *chlorographa.* *fumigata.* *aurisparsa.* *comma.* *aebutia.* *dione.* *terentia.* *georgi.* *niobe.*

L. lignea *Vollenh.*, unknown to me in nature; a narrow-winged species, with grey-black-margined hindwing, without costal spot on the forewing, but with the subapical spot prolonged into a band. The whole underside of both wings powdered with dark brown-grey. Very rare. Minahassa, North Celebes.

lignea.

2. Genus: **Leuciacria** *R. & J.*

This interesting genus is very nearly allied to *Elodina*, from which it differs in the broader, shorter cell of both wings and in the second subcostal vein arising before the apex of the cell of the forewing. Only one species known.

L. acuta *R. & J.* (73 a). Under surface of the forewing slightly glossy, thereby recalling the South American *Leptophobia*. Cell of the forewing almost imperceptibly tinged with yellow. Hindwing as in most *Elodina* with yellow, sharply defined costal margin. The black apical margin of the upper surface feebly transparent. Only a few specimens known, which were discovered by Meek at an elevation of over 6000 ft. in British New Guinea.

acuta.

3. Genus: **Elodina** *Fldr.*

Small, delicate, mostly milk-white, rarely yellow or black butterflies with pointed forewing. The second subcostal branch arises at a shorter or longer distance beyond the apex of the cell. The life-history of the species is not known. The forms hitherto found are indigenous to the Australian faunistic region and its subregions and exclusively inhabit the lowlands.

egnatia. **E. egnatia** *Godt.* (= cirrha *Bdv.*) is the first described species. Shape of the wings and appearance similar to *angulipennis* (62 e, angulipes on the plate). Markings as in *anticyra* (62 e), but with proximally straight brown distal margin to the forewing. Very rare, South Moluccas (Amboina, Ceram). — As an island *bouruensis.* race **bouruensis** *Wall.* (62 g) approaches it very nearly. Upper surface as under, except that the blackish tinge extends over the whole apical part of the wing. Buru Island.

dispar. **E. dispar** *Röb.* is a very rare, sexually dimorphic species from Bangkai near Celebes. Both sexes with narrow wings; ♂ above with almost triangular apical spots, beneath white; ♀ with very broad, proximally straight distal margin on the upper surface, occupying one-third of the wing, which is repeated also on the under surface.

therasia. **E. therasia** *Fldr.* A distinct species, of the size of *pasarga* (62 e), but with narrower wings, very broad but short apical spot on the forewing, which is very weakly repeated beneath, reduced to a narrow band. Halmaheira.

E. hypatia. Distributed over the whole of New Guinea and the islands off it, inclined to form local *sada.* races, of which quite a number are probably yet to be discovered. — **sada** *subsp. nov.* (62 e), with the sub- *litana.* apical spot on the underside of the hindwing scarcely indicated. Waigeu Island. — **litana** *subsp. nov.* Cell of the forewing above with darker dusting, under surface of the forewing with very broad black subapical band. *mulliercula.* Key Islands. — **mulliercula** *subsp. nov.* As the preceding, but with black apical margin and narrow, but *pasarga.* continuous subapical band on the forewing. British New Guinea. — **pasarga** *subspec. nov.* (62 e). The largest known white form of the genus, duller, more chalky than milky white. ♀ with relatively broader subapical band on the forewing beneath and light ochre-yellow upper surface to the hindwing. Common in the *hypatia.* woods on the coast of New Guinea, where it flies slowly, but with restless, wavering flight. — **hypatia** *Fldr.* is a normally smaller race with paler black markings on the under surface of the forewing and the under surface of the hindwing of the ♀♀ whitish instead of yellowish. Dutch New Guinea.

perdita. **E. perdita** *Miskin* (62 g) is perhaps also a race of *hypatia.* Queensland.

andropia. **E. andropia** *Btlr.* (62 f). A parallel species to the preceding, described from British New Guinea. — *hydatis.* **hydatis** *subsp. nov.* is a rare, normally larger local form from German New Guinea, in which the ♀ instead of the black marginal band bears only five large brown submarginal patches on the upperside of the hindwing.

namatia. **E. namatia** *spec. nov.* (62 e) possibly replaces *andropia* on Waigeu Island; the ♀, however, has no black markings on the milk-white hindwing and the black subapical band of the forewing beneath is scarcely half as broad as in *hydatis.*

umbratica. **E. umbratica** *Gr.-Sm.* shows beneath no sign of a subapical band on the forewing, and the black distal margin of the wing is more uniform. Solomons, Ulawa Island.

argypheus. **E. argypheus** *Gr.-Sm.* With very broad black bordering also to the costal margin of the forewing and the distal margin of the forewing proximally still straighter, also with a sharply curved costal and subapical band on the forewing beneath. Solomons, Guadalcanar.

signata. **E. signata** *Wall.* (62 d). A distinct, small species with black forewing containing a large white discal patch. New Caledonia.

angulipennis. **E. angulipennis** *Luc.* (62 e, where the name is erroneously spelt *angulipera*). The dry-seasonal form *pallene.* Hewitson named **pallene** (62 f); this has larger black patches on the under surface of the forewing. Queensland, New South Wales, Victoria.

padusa. **E. padusa** *Hew.* (62 d). With fine black distal margin to the forewing extending into the anal angle and large, isolated subapical spot on the forewing beneath. Queensland.

parthia. **E. parthia** *Hew.* (62 d). Forewing with black distal margin sharply dentate proximally. Under surface of the hindwing sand-coloured, tinged with grey-yellow or red-brown according to the time of year. In the whole of Australia.

quadrata. **E. quadrata** *Btlr.* approaches *padusa Hew.*, with longer wings, more quadrate apical spot, which is proximally less emarginate, the black distal margin as in *padusa* continued into the anal angle, the cell of the forewing yellowish. Under surface similar to that of *angulipennis*, but the whole cell yellow. Hindwing with a black cell-dot. Sydney.

walkeri. **E. walkeri** *Btlr.* is said to be allied to *perdita*, but without incised black distal margin to the forewing. Under surface of the forewing silver-white with three blackish subapical spots and the cell suffused with saffron-yellow as in *parthia.* Hindwing with black dot at the apex of the cell and 4—5 small blackish submarginal spots. Port Darwin, North-West Australia.

baudiniana. **E. baudiniana** *Btlr.* Smaller than *perdita*, above snow-white with smoke-grey costal margin to the forewing, the basal part of which wing appears flesh-coloured. Distal margin shorter than in *walkeri* and the row of dots on the hindwing beneath more indistinct. Port Darwin, probably only a seasonal form of the preceding.

E. primularis *Btlr.* (62 g) is the only species of the genus which has both surfaces light sulphur-yellow. The forewing is ornamented above with a moderately broad, proximally dentate costal and distal border, moreover the hindwing has often 4—5 brown marginal spots. New Lauenburg (= Duke of York). — **citrinaris** *Gr.-Sm.* is a local form from New Pomerania (= New Britain) with uniformly broad distal margin to the forewing and without black subapical band on the under surface. — **incisa** *subsp. nov.* is the race from New Mecklenburg (= New Ireland) with proximally strongly dentate marginal band on the forewing. — *primularis* flies sluggishly on open places in the woods, where it rests on leaves of the lower bushes (Ribbe). *primularis. citrinaris. incisa.*

E. pseudanops *Btlr.* (62 d). Both sexes beneath milk-white with broad, black, semicircular submarginal band, which at the anal margin extends to the base of the forewing and encloses an oblong, distally incised pearl-white spot. ♀ above black with an irregular yellow-marked band in the disc of the forewing and a large, roundish basal spot on the hindwing. New Caledonia, Lifu. *pseudanops.*

4. Genus: **Parelodina** *gen. nov.*

Differs from *Elodina* in the second subcostal vein of the forewing arising at the apex of the cell. Otherwise like *Elodina,* but less rich in species; it may be assumed that some of the forms treated under *Elodina,* which I have not been able to see in nature, belong here.

P. pura *Gr.-Sm.* Forewing with grey-black apical spot, which proximally is only feebly dentate. Under surface silver-white, at the base of both wings slightly suffused with yellow. Pura, Alor, Flores, Adonara. *pura.*

P. invisibilis *spec. nov.* One of the smallest known Pierids. Upper surface pure white, tinged with red-brown at the costa. The black apical spot is formed much as in *anticyra* (62 e). Under surface of the forewing as in all *Elodina* with yellowish tinge and a roundish black, bipartite subapical spot, which in the ♀ is prolonged into a band. Underside of the hindwing in the ♀ light ochre-yellow. Wetter. *invisibilis.*

P. effeminata *spec. nov.* Habitually somewhat smaller than *pasarga* (62 e), but blue-white, with a silky gloss, instead of dull yellowish, the anterior half of the cell densely scaled with brown-black. The black distal margin of the forewing more deeply dentate proximally. Under surface of the forewing only slightly yellow, hindwing of the ♀ pure white. German New Guinea, rare. *effeminata.*

P. anticyra *spec. nov.* (62 e). Under surface of the forewing and the whole upper surface of the hindwing light yellowish. Forewing with narrow black costal margin and very broad black submarginal band. Roon Island and Mafor in Geelvink Bay. *anticyra.*

5. Genus: **Delias** *Hbn.*

This genus, which is very rich in species, recalls in many respects in the shape of the wings, the colouring and the mode of flight, the South American *Pereute.* The *Delias* are a characteristic feature of the Indian fauna. They enliven the woods and their borders, as *Appias* and *Catopsilia* predominate at the river-banks, fly often round the tops of the forest-trees, are fond of resting on leaves and flowers (for instance on those of the Cinchona-tree, the Lantana) or in rarer cases speed over grassy plains in wild, irregular flight (*battana* in South Celebes).

But most species fly slowly and quietly from flower to flower and often do not even leave the bush on which, frequently to the number of many hundreds, they emerged from the pupa (*belisama* on Java). Comparatively few species are distributed over large tracts of country, most remain local or insular; they are inclined to geographical variation, even on the same island (*bromo, fruhstorferi* in East Java and *crithoë, momea* in West Java, which are so different that they were described as separate species). But they are by no means particular as to their place of flight and we meet with them at the seashore in mangrove thickets (from whence they often fly out even over the sea), on the high volcanoes of the Malayan Archipelago and in the Himalayas, where they are common up to 8000 ft., but also ascend to 10 and even 11,000 ft.

The eggs are laid on the underside of leaves, often 20—30 in parallel rows. Larva cylindrical with two rows of long hairs, lives on mistletoe (Loranthus longiflorus); but one species (*eucharis*) was also observed on Hibiscus chinensis. Pupal stage usually lasts 10 days, pupa fastened at the end of the tail, with the head upwards, often very abundant on tree-trunks, branches and even walls.

a. Under surface of the hindwing yellow with mostly whitish submarginal spots without red basal spot.

D. agostina inhabits exclusively the lower spurs of the Himalayas and neighbouring ranges. Three races are hitherto known: **agostina** *Hew.* (54 d). ♂: upper surface white, forewing with the veins only distally broadly covered with black. Under surface with all the veins black. Hindwing canary-yellow with narrow white, black-edged distal half. ♀: upper surface of the forewing grey with lighter cell and discal area, a row of 5—6 white *agostina.*

submarginal dots; the hindwing above in the dry-season-form light orange and in the wet form dark orange-colour.
infumata. Inhabits the valleys of Sikkim, where it occurs from March to December. — **infumata** *Fruhst.* (54 e) has almost entirely black forewing and the distal border of the hindwing often extends nearly to the wall of the cell. Assam,
annamitica. Tenasserim, taken in May at an elevation of 4000 ft. — **annamitica** *Fruhst.* (54 e), with the forewing somewhat less suffused with black, the under surface only a little darker than in Sikkim examples. The ♀ has the upperside of the forewing uniformly and delicately suffused with light grey, that of the hindwing pale yellow with sharply defined distal margin. Locality: South Annam, February, at about 5000 ft., where they had chosen the summit of a treeless hill covered with a few native huts as the scene of a nuptial flight. The swift-winged butterflies came out of the neighbouring wood and flew over a marshy swamp, only sparsely overgrown with brushwood, and then suddenly darted away uphill, high above the grass roofs of the houses. Only when a butterfly occasionally strayed away in the ardour of the pursuit were my hunters able to catch it and it took us over an hour to capture some three ♀♀ and ♂♂.[1])

singhapura. **D. singhapura** *Wall.*, usually somewhat larger than the preceding, with uniformly grey-black-powdered distal part of forewing and lemon-yellow under surface to the hindwing. Very rare, hitherto only the type spe-
indistincta. cimen is known from Singapore. — **indistincta** *Fruhst.* (55 d), forewing beneath with the black shading twice
agoranis. as broad as in the preceding. In North and South Borneo, not very rare. — **agoranis** *Gr.-Sm.*, with more sharply defined, deep black apical border and especially broad submarginal bands on the underside of the hindwing; inhabits Tenasserim and the Shan States.

themis. **D. themis** *Hew.*, from Mindanao, with the deep black distal margin more sharply expressed but essen-
soteira. tially narrower than in **soteira** *subsp. nov.* (55 d), from Luzon, which is also distinguishable beneath by much narrower white circumcellular spots on the forewing.

kuehni. **D. kuehni** *Honr.* approximates to *themis*, with the forewing entirely black beneath. Hindwing with
sulana. three light yellow submarginal spots. Bangkai Island, near Celebes, only a few specimens known. — **sulana** *Stgr.*, a good local form, with larger white spots on the forewing and six yellow and yellow-grey submarginal patches on the hindwing beneath. Only 1 ♂ known; Sula Mangoli.

baracasa. **D. baracasa** *Semp.*, a small species parallel to *themis* and *agostina*, which has advanced southwards to Sumatra. The under surface of both wings white with narrow black bands and a thin submarginal band of the same colour. Only the base of the hindwing is suffused with greenish yellow. Hitherto only 1 ♂ known, from
cathara. South-East Mindanao. — **cathara** *Gr.-Sm.* (55 d), a strongly darkened local form from the Kina Balu, with entirely
danala. yellow upper surface to the hindwing and confluent black bands. — In **danala** *Nicév.* (= karo *Hag.*) (55 d, e), from the mountains of Sumatra, there is a conspicuous row of white subapical dots on the upperside of the forewing, which beneath assume a yellow colour, as is also the case with the submarginal spots on the under surface
dives. of the hindwing in the ♀♀. — **dives** *Nicév.*, from Penang. Upper surface of the forewing similar to that of *cathara*, only slightly scaled with black. Under surface of the hindwing light ochre-yellow without submarginal band and with only a narrow black distal margin. Whether it is a distinct species cannot be decided with certainty, as *dives* is not known to me in nature.

dorimene. **D. dorimene** *Cr.* (55 b). The figure shows the upperside of the ♂ and the underside of the ♀. The under surface of the ♂♂ only differs from that of the ♀♀ in the narrower black distal margin and smaller yellow patches.
rothschildi. Common on the South Moluccas: Amboina, Ceram. — On Buru occurs the race **rothschildi** *Holl.*, with smaller white submarginal spots on the forewing. On the hindwing, however, these patches are enlarged and the black marginal band is broader. Only 1 ♀ known.

echidna. **D. echidna** *Hew.* (52 c), from Ceram, has apparently not been found again since 1861, as only the type in the British Museum is known. The upper surface according to Hewitson is white, with black costal margin and finely dentate distal margin to the forewing. Hindwing likewise with black distal margin, which proximally is finely dusted with grey.

melusina. **D. melusina** *Stgr.*, a mountain species from the north of Celebes, has beneath some resemblance to *echidna*, but the whitish subapical spot of the forewing is absent. All the submarginal spots are strongly reduced, the base and the discal area of the forewing blue-grey. The upper surface is blue-white, with black areas on both wings.

b. Under surface of the hindwing without red or yellow basal spot, but with red or yellowish submarginal spots.

eucharis. **D. eucharis** *Drury* (51 a). Characterised by the gorgeous submarginal spots, which are above rose-coloured, beneath light red bordered with white, distally somewhat pointed, otherwise quadrate. The apex of the forewing and the upper surface of the hindwing suffused with a beautiful light yellow. The butterfly lays 20—30 eggs on the underside of leaves in parallel rows. The larvae are polyphagous and are often found in thousands, but suffer from ichneumons and parasitic flies. The pupae are fastened closely to the leaves by

[1]) Cf. addenda.

the tail, but with the head upwards; the pupal stage lasts about 10 days. The butterfly flies all the year round, in parts of northern Ceylon in great abundance, and is very fond of the flowers of Lantana, on which it hangs with the wings half open. *eucharis* ascends in India to 7000 ft., reaches in Kashmir the Palearctic Region and varies but little.

D. hyparete, a species distributed from the Himalayas to Formosa and in the south from the Malay Peninsula to Celebes in a large number of local forms, some of which are sharply separated. — **peirene** *Fruhst.* (51 b), from Formosa, where it occurs up to about 4000 ft., has on the under surface a more extended white submarginal area than *luzonensis*. Specimens also occur with light ochre-yellow or orange-coloured submarginal spots on the underside of the hindwing (**maenia** *form. nov.*). — Of **luzonensis** *Fldr.* (51 d, e) the larva is known. This is entirely lemon-yellow, only head, legs and anus being black, the dorsum with yellow hairs. It lives on Averhoa bilimbi, where it is often found hanging by long threads. — **mindorensis** *subsp. nov.* has as a rule fewer and smaller red submarginal spots on the hindwing; similar specimens also occur on Cebu, Bohol and Camotes. — **mindanaensis** *Mitis* (51 c) is a small form with strongly darkened ♀♀, less red on the under surface in the figured dry-season-form and broader red in the larger rainy-season-form. Mindanao, South Philippines. — In **palawanica** *Stgr.* (51 b) all the veins and the distal margin of the hindwing are more broadly black. Palawan Island. — **lucina** *Dist.* (= jolana *Stgr.*) (51 d), from the Sulu Islands, is distinguished by its almost entirely white upper surface and the absence of yellow colour on the hindwing beneath. — **stolli** *Btlr.*, from southern China, has the ♀ almost entirely black above and on the under surface of the hindwing the yellow basal tinge reaches to the black distal margin. — Very close to it is **ciris** *subsp. nov.* (51 b), whose ♂♂ are distinguished by a broad black apical area and whose ♀♀ are conspicuous by the darker cell-area on the forewing. Siam, Cochin China, Tonkin, Tenasserim. In Bangkok and Saigon *ciris* was quite an ornament to the gardens and pleasure-grounds, where it flew up and down under the shade of the high Ficus, alighting from time to time on the upperside of the leaves. — **hierte** *Hbn.* (51 a), from the mainland of India, ascends in the Himalayas to 6000 ft., but is no longer common at this extreme limit of its range. — As **devaca** *Moore* an aberration is known with the cell of the hindwing beneath suffused with scarlet, whilst ab. **indica** *Wall.* denotes an aberration with almost entirely white apex to the forewing. — **ethire** *Doh.* is a very light race from South India, which has also been taken in Bengal, beneath with light lemon-yellow tinge on the hindwing and very large yellow subapical spots on the forewing. — **metarete** *Btlr.* is the strongly darkened geographical race from the Malay Peninsula and Singapore. — **despoliata** *subsp. nov.*, from Sumatra, very nearly approaches it, but the red spots on the underside of the hindwing are much less conspicuous, often only 3 instead of 6 submarginal spots present, moreover the proximal black bordering of these is distinctly narrower. — In **diva** *Fruhst.* (51 b), from North Borneo, the yellow shade on the hindwing again reaches the much broader proximal black bordering of the submarginal red spots, which are still more prominent. — All the islands round Sumatra produce distinct local forms, of which **haemorhoea** *Voll.*, from Banka, is characterised by orange-yellow basal spots and only 3 short, broad red submarginal patches on the hindwing beneath. The forewing remains almost entirely white. — **simplex** *Btlr.*, locality unknown, has the proximal third of the hindwing beneath pale chrome-yellow. — **jataka** *Fruhst.* (51 d), from the Batu Islands, has the forewing grey-black and the under surface of the hindwing dark lemon-yellow throughout. — **hypopelia** *Hag.* differs from *jataka* by a row of yellow submarginal strigae on the forewing and much more broadly black veins, as well as a grey-yellow base to the hindwing; from the Mentawei Islands, only 1 ♀ known. — **niasana** *Kheil* (51 d), very light in the♂, whilst the ♀♀ show above broad black veins, yellow subapical strigae and densely scaled interneural areas. An aberration with yellow instead of red submarginal spots was named **amarilla** by Kheil. — **hyparete** *L.*, from Java and Bali, is very variable; scarcely two specimens agree. The rainy-season-form (51 c) is broadly margined with black above, whilst the dry-season-form from East Java, **aureivenula** *form. nov.* (51 c), shows large yellow apical strigae and the upper surface of the hindwing is suffused with light yellow. Very common in Java, where the species ascends to 2500 ft. and is very common at the edges of open woods. Larva ochre-yellow with fine lateral hairs of the same colour. Head and legs black. Pupa beautiful light yellow, 12 ventral spines black, the others yellow (Vollenhofen).

peirene. maenia. luzonensis. mindorensis. mindanaensis. palawanica. lucina. stolli. ciris. hierte. devaca. indica. ethire. metarete. despoliata. diva. haemorhoca. simplex. jataka. hypopelia. niasana. amarilla. hyparete. aureivenula.

D. rosenbergi *Voll.* (= chrysoleuca *Mitis*) (52 a) is the Celebes representative of the *hyparete*-group, a stately species, above in the ♀ almost entirely suffused with black-grey. In South Celebes *rosenbergi* flies all the year round, in large numbers in March and April at the end of the heaviest rainy season. The larva does not differ from that of *despoliata* from Sumatra, except that it is larger, dark yellow with light yellow and white hairs, and lives on Loranthus, which is parasitical on mango trees. The butterflies first appear very early in the day about 6 or half past 6 o'clock, and then again late in the evening (Martin). — In the north of the island occurs **lorquini** *Fldr.* (= catamelas *Stgr.*) (52 b), where the species ascends from the sea-coast to 3000 ft. The black bands on the underside of both wings are broader, the cell-region with more extended black scaling.

rosenbergi. lorquini.

D. mitisi *Stgr.* is a rare species from the Sula Islands, with still darker under surface to the hindwing, which also bears larger red spots than *rosenbergi.*

mitisi.

D. periboea *Godt.* (51 e), a variable species, which is very local on Java, but in some years occurs abundantly even in large towns, such as Soerabaja and Bandong. — **wallacei** *Rothsch.* is the name of the race from Bali,

periboea. wallacei.

somewhat more broadly striped beneath, which has been erroneously described as being from Celebes in consequence of a mistake on the part of the collector DOHERTY. — **livia** *Fruhst.* (56 d) is a form discovered on Lombok at an elevation of about 2000 ft., which has always much fewer and narrower red patches on the hindwing beneath. — **pagenstecheri** *Fruhst.* may be recognised by the shorter black stripes on the under surface and the washed-out submarginal spots of the hindwing, which are more orange-coloured than red. Sumbawa, rare. — **alorensis** *Fruhst.* (52 a) is the most easterly offshoot yet known, distinguished by broader light yellow subapical spots on the forewing, dark ochre-yellow tinge at the base and a complete row of intensively red submarginal spots on the hindwing, which appear on the upperside as faint pale pink spots. Upper surface of the hindwing light yellow instead of whitish or grey-blue as in the eastern subspecies of *periboea*. Alor.

livia. *pagenstecheri.* *alorensis.*

fasciata. **D. fasciata** *Rothsch.* (51 e) is peculiar to Sumba, of Australian aspect and somewhat similar above to *argenthona F.*

sumbawana. *minerva.* **D. sumbawana** *Rothsch.*, from Sumbawa, with only one known subspecies, **minerva** *Fruhst.* (52 a), which on Lombok flies rapidly round the tops of high trees at an elevation of 2000 ft. in company with *livia*. *minerva* differs considerably from *sumbawana* in the greenish yellow instead of light orange colour and in having the submarginal red crescents on the underside of the hindwing scarcely half as broad.

splendida. **D. splendida** *Rothsch.* is a magnificent species, which beneath is deceptively like *Huphina laeta Hew.* (65 e). From Timor.

argenthona. **D. argenthona** *F.* (53 e). ♂: above with the apex of the forewing somewhat more broadly suffused with black than in *fasciata*. Hindwing with the red spots of the under surface showing through in rose-colour. The ♀ occurs in two forms, one with the upper surface entirely light yellow and another with the distal half of the hindwing entirely black: **seminigra** *form. nov.* (55 a). — **fragalactea** *Btlr.* (53 e), with red apex to the cell and somewhat broader black submarginal bands on the hindwing, may be regarded as a seasonal form, perhaps even only a casual aberration. Australia.

seminigra. *fragalactea.*

schoenbergi. **D. schoenbergi** *Rothsch.* (56 c). A species distinguished by its size and the peach-blossom-coloured tint of the hindwing, which is very rare and inhabits Bougainville in the Solomon Islands. The under surface of the hindwing is of light yellow ground-colour with weaker black discal spot and larger red submarginal spots than **isabellae** *Rothsch.* (56 d) from the island of Ysabel. — **choiseuli** *Rothsch.*, from Choiseul, with both surfaces still more broadly margined with black and with a more conspicuous black median band on the hindwing, may be regarded as a highly specialised transitional form, the ♀ of which is adorned above with a series of five roundish submarginal patches on the hindwing.

isabellae. *choiseuli.*

timorensis. **D. timorensis** is one of the most gaily coloured known species and is confined to the islands of the Timor Group. **timorensis** *Bdv.* (= vishnu *Moore*) (54 b, c), in my collection from Timor, Wetter, Babber and Kisser, *gardineri.* ♂♂ with whitish, ♀♀ with gold-yellow colour at the base of the forewing beneath. — **gardineri** *Fruhst.* (54 c), from Timor Laut, with dark ochre-yellow colour at the base and much broader black distal margin on the under surface of both wings.

poecilia. **D. poecilia** *Voll.* (54 d). Hitherto only known from the northern Moluccas. The red submarginal band *edela.* of the hindwing beneath narrower than in **edela** *subsp. nov.* (54 d) from Obi, an island form which shows above a broad deep black apical area with 5 white oblong spots and very broad black border to the hindwing, at the distal margin of which are scattered 6 white dots. The ♀ is unknown.

sacha. **D. sacha** *Gr.-Sm.*, above very similar to *edela*, but with the black distal border of both wings more reduced, bears on the under surface of the hindwing quite near to the distal margin narrow ochre-yellow spots, the basal part of the hindwing somewhat lighter yellow and the orange-coloured subanal tinge somewhat more extended than in *poecilia*. Rare on the island of Obi.

alberti. **D. alberti** *Rothsch.* (56 d) closely resembles *sacha* beneath, but the preapical spots of the forewing are more broadly white, the submarginal spots of the hindwing lighter, more than twice as broad, their proximal black bordering is broader anteriorly and the disc of the hindwing is dusted with black. Choiseul, where it occurs together with *schoenbergi choiseuli Rothsch.*

D. mysis appears to replace the Indian *hyparete* in the Papuan region and shows the same tendency as *mysis.* the latter to local variation. The oldest form is well known from Australia. — **mysis** *F.* (54 c) is characterised by the most extended black margining of both wings and the row of white subapical patches on the forewing. *aestiva.* A smaller, lighter-spotted dry-season-form was named **aestiva** by BUTLER. North Australia, Queensland. — *nemea.* **nemea** *subsp. nov.*, from Merauke, Dutch South-West New Guinea, is essentially smaller and the ♂♂ have beneath *onca.* a strikingly narrow red submarginal band, which bisects a very broad deep blue-black border. — **onca** *subsp. nov.*, *lara.* from Milne Bay (British New Guinea), forms a transition to **lara** *Bdv.*, from Dutch North-West New Guinea, from which it differs in having the red and black bands on the underside of both wings almost twice as broad. —

intermedia *Mitis*, from German New Guinea, shows in the ♂ beneath only as little proximal black bordering to the red submarginal band as *oisyme*. ♀♀ also occur with white, and others with yellow subapical spots on the under surface of the forewing. — **oisyme** *subsp. nov.* (54 d) is a small island race with almost quadrate forewing and very sharply defined bands and beautiful chrome-yellow subapical spots on the forewing beneath. Waigeu. — **cruentata** *Btlr.* closely approximates to *oisyme*, but differs from it in the much narrower red submarginal band of the hindwing. Misol. — **aruensis** *Mitis* (54 d) again approaches the mainland type, but has a longer forewing and appreciably broader spots and bands. Aru Islands. — Finally, **maga** *Gr.-Sm.* is a further well differentiated island race with the black bands on the under surface of both wings twice as broad as in *mysis* from the mainland, almost entirely yellow upper surface to the hindwing and broad, brilliant carmine-red submarginal band. Sudest Island, near British New Guinea. *intermedia. oisyme. cruentata. aruensis. maga.*

D. ennia *Wall.* (54 a), likewise only indigenous to the Papuan region, has beneath yellow instead of red submarginal bands. There are only four local races known, but the species may certainly still be looked for from other parts of New Guinea and its numerous attendant islands. Rare on Waigeu. — **jobina** *Oberth.*, with almost entirely yellow under surface to the hindwing and very broad black distal area on the hindwing beneath. Jobi Island. — **nigidius** *Misk.* (54 b), with very narrow distal area, common in Queensland. In the latter a widening of all the black and yellow bands is noticeable, especially beneath, whilst **xelianthe** *Gr.-Sm.*, with very small yellow markings on the hindwing beneath, occupies a middle place between the two as regards the shape and course of the black bands. British New Guinea. Rare. *ennia. jobina. nigidius. xelianthe.*

D. lytea *Godm.* is a charming, but rare species of the Bismarck Archipelago, without opaline gloss on the under surface, and also otherwise with duller colours, which present a mealy appearance. The ♀ is more than twice as broadly margined with black as the ♂. New Pomerania (= New Britain). — **georgina** *Gr.-Sm.* (54 b), from the Solomon Islands, appears to differ but very little. *lytea. georgina.*

D. narses *Heller* has also the base of the forewing beneath yellow and the whole distal half of the wings is sharply differentiated, deep black and with 5 almost equal yellow roundish patches. New Pomerania (= New Britain). *narses.*

D. totila *Heller* presents one of the darkest coloured species of *Delias*, with the wings half yellow, half black, and a large elliptical white spot on the upper surface of the forewing. The base of the forewing beneath is white, but the upper surface of the hindwing is deep black almost all over, except for a slightly lighter, yellow-powdered and very restricted basal area. New Pomerania. *totila.*

D. caliban *Gr.-Sm.*, from Fergusson Island, also belongs in this group, but is much larger than *narses*, in shape and on the upperside very similar to *belisama Cr.*, from Java. Under surface of the forewing with entirely black distal part and 3 yellowish white subapical dots. The proximal third of the hindwing yellowish, but little powdered over, the whole of the broader distal part deep black with white subcostal spot. Only in English collections and but 2 specimens known. *caliban.*

D. iere *Gr.-Sm.*, a peculiar and rather plain *Delias*, so far very rare, which is intermediate between *mysis* and *ennia* and has a similar scheme of marking to *gabia*. The under surface is characterised by yellowish subapical patches in a black apical area on the forewing, the upper surface of the hindwing is light canary-yellow with relatively narrow black distal margin, which is divided by delicate orange spots. British New Guinea, discovered by A. S. Meek. *iere.*

D. euphemia *Gr.-Sm.* Hitherto only known from Biak Island in Geelvink Bay, a species which forms a transition from *mysis* to *bagoë*, without the yellow subapical spot on the underside of the forewing of the latter. *euphemia.*

D. bagoë inhabits the Bismarck Archipelago. There are only two geographical races known: **bagoë** *Bdv.* (= eurygania *Godm. & Salv.*), from New Mecklenburg, with narrower apical spot, but entering further into the cell, on the forewing beneath and much narrower black bands on the upper surface of the hindwing than **nusana** *Fruhst.* (55 a), from the island of Nusa Laut, which beneath is more pronounced and extended red, above more broadly margined with black, than *bagoë*. *bagoë. nusana.*

D. salvini *Btlr.* (55 a) represents *bagoë* on New Pomerania and differs from it by a white subapical band on the forewing beneath.

With **D. candida** *Voll.* (55 b) begins the series of species peculiar to the Moluccas; *candida* has entirely white upper surface to both wings, through which, however, the black and yellow markings of the under surface are distinctly visible. Sexual dimorphism is very prominent in all the Moluccan species, compare the entirely black-grey ♀, which only bears white submarginal spots. The underside bears brighter colours; the proximal half of the wings is yellowish grey, the distal half black, the forewing bears white submarginal lunules and the hindwing dark ochre-coloured ones. Batjan, Obi. Not rare. *candida.*

D. caeneus *L.* is divided into two races over the South Moluccas. **caeneus** (= plexaris *Don.*) (53 d) occurs very commonly on Amboina, Ceram and Saparoea. In the ♀ the grey basal dusting of the forewing reaches *caeneus.*

philolis. the costal margin, whilst in **philotis** *Wall.* (53 d, e), from Buru, it only extends a little beyond the base of the cell and only below the median is widened in the shape of distinct white stripes. The base of *philotis* is beneath lighter and purer yellow, on the other hand the red spot in the cell of the hindwing is much reduced and the black submarginal region is extended.

duris. **D. duris** *Hew.* (53 d). Hitherto only known from Ceram, where the species appears to occur in two seasonal forms; for I have before me ♂♀ with moderately narrow red submarginal band on the hindwing and broadly developed black margins and specimens with very broad and light red bands, without or with only a little proximal black bordering and very large dark instead of light yellow subapical and cell-spots on the underside *aleria.* of the forewing (= **aleria** *form. nov.*).

funerea. **D. funerea** *Rothsch.* (= plateni *Stgr.*) is somewhat larger, has the under surface of the forewing entirely *buruana.* white, but that of the hindwing entirely black. Batjan. — **buruana** *Rothsch.*, the race from Buru, is unknown to me in nature.

isse. echo. **D. isse** *Cr.* (55 a), common on the South Moluccas. The under surface is similar to that of **echo** *Wall.* (53 e), from Buru, but the hindwing has a yellowish area of almost double the width, extending beyond the cell, and the submarginal spots are twice as broad and ochre-yellow.

ribbei. **D. ribbei** *Röb.*, from the Aru Islands, is a very rare species, of which *sacha Gr.-Sm.* is perhaps a local form. The white subapical spots on the underside of the forewing in *ribbei* are broader than in *echo*, the black submarginal band of the hindwing is narrowed, whilst the submarginal spots are strongly enlarged and assume a quadrate form.

diva. **D. diva** *R. & J.* (56 f), one of the most gaily coloured species. The upper surface is plain white, with broad, deep black, apical transverse area on the forewing. In the ♀ some yellowish dots placed on the distal *emilia.* margin of the hindwing are also noticeable. British New Guinea. — **emilia** *R. & J.* (= Tachyris weiskei *Ribbe*), a paler local form from British New Guinea, with grey instead of black distal margin on the hindwing beneath, which is ornamented with larger yellow patches.

enniana. **D. enniana** *Oberth.* (= ennia *Wall.* pt.; dorothea *Mitis* pt.) (54 a); hitherto only known from Waigeu, where it is not very rare. ♂: the upper surface white with sharply cut off, black distal margin to the forewing, which bears a few white dots. ♀ with black, mostly isolated transverse spot at the end of the cell, with fairly uniform black distal margin and mostly dull white upper surface to the forewing, upperside of the hindwing suffused with yellow.

diee. **D. dice** *Voll.* is a very rare species, whose ♂♂ are not yet known. The figure (54 a) represents a local form of the ♀ from Kajumera Bay, Dutch South-West New Guinea. On the under surface the black distal area of the hindwing is widened, sharply defined proximally and bears, like the apical area of the *dorothea.* forewing, a row of 5—6 yellowish patches in the middle. — **dorothea** *Mitis* (55 e). The hitherto unknown ♂ is figured here for the first time. There exist ♀♀ with entirely white and others with yellowish upper surface to the hindwing. The short black subapical band of the forewing beneath is commonly not united with the distal band, moreover the intensity of the yellowish subapical spots varies. Waigeu. Rather common.

gabia. **D. gabia** *Bdv.* (55 c) is likewise figured here for the first time. The upper surface is pure white with the black distal margin, present also beneath, on which, however, the white dots can scarcely be recognised. ♀ still unknown. The species comes from Offak on Waigeu. Quite a number of local races deserve mention. — *dorylaea. felsina.* **dorylaea** *Fldr.* (= hippodamia *Wall.* ♂) (55 c), with still broader black distal margin. Aru Islands. — **felsina** *subsp. nov.* (55 c), from Kajumera Bay, in Dutch New Guinea. The upper surface of the ♀ is dull yellowish *seribonia.* white, forewing with 3 large dots in the blue-black distal margin. — **scribonia** *subsp. nov.* (55 c) is adorned with more vivid orange-yellow tinge on the underside of the hindwing. The ♂♂ vary on the under surface, having in the marginal band of the hindwing between the veins sometimes whitish spots (forma *albipunctata Hagen*); sometimes orange-yellow (forma *flaripunctata Hagen*), sometimes no spots at all (forma *impunctata Hagen*). *zarale.* Not rare in German New Guinea, and flies especially in January and February. — **zarate** *Gr.-Sm.* has less orange yellow colour on the hindwing, but larger yellow patches on the under surface of the forewing. Milne Bay, British *banlina.* New Guinea. — **bantina** *subsp. nov.*, from Kiriwina, D'Entrecasteaux Islands, differs in the smaller form and *callistrate.* broader black marginal bands. — **callistrate** *Gr.-Sm.* (55 d) is a large race from Fergusson Island, with very broad black spots.

geraldina. **D. geraldina** *Gr.-Sm.*, a pretty species, ♂ with pure white upper surface to the forewing, bordered by a distal margin which is costally broader, and which in the ♀ also surrounds the hindwing. Under surface: forewing white, with black distal third, hindwing light yellow, in the black distal area submarginal rows of small yellow dots. Only known from the Saddle Mountain, German New Guinea.

altivaga. **D. altivaga** *Fruhst.* (55 c, incorrectly named *gabia* on the plate, under surface), a mountain species from West Java, hitherto only observed on Mt. Gedé at 5000 ft., where it flies rapidly

except when flying round the tree-tops in search of the epiphytic mistletoe, its food-plant.

c. Under surface of the hindwing with yellow basal spot.

D. mysa *F.* (54 f) is the oldest-known species of a small group of *Delias* which has spread from Australia to Sumatra. *mysa*-♂ is above scarcely distinguishable from *fruhstorferi*-♂ (56 d), but beneath as in the ♀ it is grey-black all over, with yellowish basal half to the forewing and 6 orange-coloured, isolated small submarginal spots on the hindwing. In Australia distributed from Cairns in Queensland to Sydney, and locally very common. *mysa.*

D. momea. A pretty species only known from Java and Sumatra, where it occurs at elevations of 4-6000 ft., flying slowly and heavily. — **fruhstorferi** *Honr.* (56 d), hitherto only found in the Tengger Mts., East Java, has a white under surface to both wings, a broad white discocellular and large white subapical spots on the forewing. Hindwing: the submarginal spots yellowish, large, distally pointed. Central area broadly white, the base and distal area grey-black. — **momea** *Bdv.*, from West Java, where it is not rare at Mt. Gedé, has the under surface yellow instead of white, with small white subapical dots. The discocellular is black, only ornamented with small white dots, hindwing distinctly grey-black with diffuse whitish median spots and small submarginal dots. — **hageni** *Rogenh.* (= datames *Nicév.*), from the mountainous parts of Sumatra, almost agrees with *momea* beneath, except that the hindwing of the hitherto undescribed ♀ is completely black, and its upper surface is more broadly margined with deep black, with hardly a trace of white dots and the basal part of the hindwing is suffused with blue-grey. *fruhstorferi.* *momea.* *hageni.*

D. itamputi *Ribbe* (56 f) (name from the Malayan = black-white). Sexes dimorphic, ♂ above pure white with black, oblique, very broad apical spot. ♀ above as beneath, only with yellowish white base to both wings and in the distal margin of the hindwing without the subterminal row of white patches. Flies in May. Aroa River, British New Guinea. *itamputi.*

D. hypsomelas *R. & J. i. l.* (56 f). ♂ above as the preceding species, under surface black with 2 yellow apical dots on the forewing, 5 small oblong white subterminal streaks on the hindwing. Locality as the preceding. *hypsomelas.*

D. aroae *Ribbe.* ♂: upper surface as in the two preceding, except that the distal margin of the otherwise pure white hindwing is adorned with a narrow black band, which is somewhat narrowed from the costa to the anal angle. The under surface as in *geraldina Gr.-Sm.* and *cuningputi*, but with white median and basal region on the forewing and a strongly divided black basal part to the hindwing, on which are placed 2 larger yellow patches. The subterminal spots of the hindwing pure yellow, isolated, much larger than in *cuningputi*. Rothschild has figured in Novitates 11 what is supposed to be the ♀, the under surface of which bears 3 median and 4 submarginal patches, which are much smaller and more orange-yellow than in the ♂. British New Guinea. *aroae.*

D. cuningputi *Ribbe* (56 e) (name from the Malayan = yellow-white). ♂: upper surface grey-white with broad distal margin on both wings, which on the forewing encloses 3 small white subapical dots, hindwing with very broad white cilia. ♀ above almost like the ♂, but beneath richer in colour, as all the submarginal spots and the base of the forewing are tinged with light orange-yellow. The white median area of the hindwing deeply incised distally. British New Guinea. *cuningputi.*

D. iltis *Ribbe* (56 e), one of the most brightly coloured species, the pattern of whose hindwing recalls the head-dress of Indians. Upper surface pure white with black discocellular and oblique black apical border, in the centre of which are placed 2 white dots. The ♀ is more broadly margined with black. British New Guinea. *iltis.*

D. georgina *Fldr.* A hitherto rare species from the Philippines, of which only 2 ♀♀ are known, taken in March on West Luzon at a height of 600 m. *georgina* is distinguished by the rounded form of the wings and the uniformly spotted under surface, which on the hindwing differs from *battana* in the absence of the black basal dusting, but broader black bands. — **battana** *Fruhst.* (54 f). The ♂♂ are above lemon-yellow with 2 rows of black spots interrupted by yellow, whilst the under surface is paler yellow and has the same latticed pattern as the ♀. ♀♀ somewhat variable: there occur pale lemon-yellow and more rarely ochre-yellow specimens (f. **auricoma** *form. nov.*). *battana* was commonest in misty or even rainy weather. The butterflies came hurrying out of the neighbouring wood, straight down from the trees, and were carried by the wind over an adjoining heath. Here they could then be captured with little trouble and the natives even brought me uninjured specimens taken with their hands. Once in the net these *Delias* remained completely passive and sat quietly with the wings folded. All this was changed in sunny weather. The butterflies flew then at an inaccessible height, encircling the tops of flowering trees, and we only succeeded by chance in catching one of them. Flies in February, March at 5-6000 ft. on the peak of Bonthain. South Celebes. Not rare. *georgina.* *battana.*

D. orphne *Wall.* has a white instead of yellow under surface to the forewing and the black bands on it only extend to the apex of the cell. Hitherto only 1 ♀ known, which Wallace caught on Mt. Ophir, Malacca. — *orphne.*

cinerascens. **cinerascens** *Mitis* (54 e) is a rare local form from the Kina Balu in North Borneo. Upper surface of the ♂♂ white with slight grey apical shade. ♀ broadly margined with black, with grey base to the forewing and yellowish discal *simanabum.* area on the hindwing. The under surface of the ♀♀ is always somewhat darker than in the ♂ figured. — **simanabum** *Hagen*, from the tableland of Sumatra, is the poorest in colour and markings, nevertheless the most specialised local form of *orpline*, with yellowish white upper surface, white under surface to the forewing, which only bears 2 yellowish apical spots, and pale yellow under surface to the hindwing, on which vestiges of the black apical spots in the middle of the wing still remain. Only 1 ♀ known.

chrysomelaena. **D. chrysomelaena** *Voll.* (55 b), from Batjan, where it is rather rare, has above only a slight black tinge at the apex of the forewing and the distal margin of the hindwing. The under surface is characterised by broad yellow areas on a black ground.

clathrata. **D. clathrata** *R. & J.* (56 e). ♂ above white, forewing, especially in the apical region, very broadly, hindwing narrowly margined with black. In the ♀ the black area extends beyond the cell-wall of the forewing. British New Guinea.

mira. **D. mira** *R. & J.*, a very rare species, somewhat larger than the preceding, in the ♂ only a small basal area on the otherwise black upper surface remains grey-white, whilst the hindwing on the contrary is only black in the distal third. Under surface similar to that of *clathrata*, but the white basal area only extends into the cell, the subapical band is much more extended, the hindwing bears only a black discal spot, its anterior part is shaded with brown and only the extreme anal region remains white. The ♀ has a more extended white basal region on the forewing and is ornamented on the latter with 6 submarginal spots. Flies in May. Only 1 pair known.

eichhorni. **D. eichhorni** *R. & J.*, from the same district, above marked somewhat like *cuningputi*. ♂: under surface of the forewing orange-yellow with isolated black dot at the apex of the cell and uniform black distal margin, relatively narrow, with 4 white subapical spots. Hindwing predominantly black with peculiarly angled white discal part, white basal spot and 6 large hexagonal submarginal patches. British New Guinea.

D. belladonna. A widely distributed species, principally inhabiting the mountains, which by its size always attracts the attention of travellers, consequently more is known of its habits than of those of any other *Delias*, although we known nothing at all as yet concerning the earlier stages. In the Indian empire 5 local races *sanaca.* may be distinguished: **sanaca** *Moore* from the western Himalayas as the lightest, forewing sometimes even with *flavalba.* white cell (= forma **flavalba** *Marsh.*), hindwing mostly white with light yellow tinge at the inner margin. Even the darkest specimens bear on the hindwing beneath still broader white bands than even *perspicua*. *sanaca* appears in the early summer, is local, but common in certain places. The butterflies fly sometimes like swallows or chase each other, are fond of circling round the tops of trees, on which they settle. Their scent somewhat resembles that of certain pears. In May and June they were observed in Mussouri at elevations of from 5—8500 ft., both the darkest and lightest specimens at the same place in one morning at *surya.* open spaces in the midst of oak-woods. — As form **surya** *Mitis* an aberration with orange-coloured patches on *belladonna.* the hindwing has been described; and **belladonna** *F.* (= horsfieldi *Gray*) is the name given to specimens of medium size with a row of small white discal patches on the forewing and much larger quadrate spots on the hindwing. *hearseyi.* Nepal, parts of the western Himalayas and Sikkim. Chance aberrations with red instead of yellow stripes on *boyleae.* the hindwing have been named **hearseyi** *Btlr.*, **boyleae** *Btlr.* and those with orange-coloured spots **amarantha** *amarantha.* *Mitis*. — The name **ithiela** *Btlr.* is best restricted to the dark Sikkim race, which only varies moderately in the *ithiela.* larger or smaller extent of the white discal spots and the grey or yellowish inner margin of the hindwing. *ithiela* is extremely common in Sikkim from May to August in the hot parts from 2—4000 ft., where it flies slowly at *berinda.* the banks of rivers, often resting on moist sand-banks. — I separate here as **berinda** *Moore* the well defined, darkest Indian race, which I received in great numbers from Assam. I possess from Assam only ♂♂ with grey, or even deep-black inner margin to the hindwing above. Also the under surface of the hindwing is more melanotically coloured, the white discal spots, especially the yellow submarginal patches, being always much smaller. ♀ above almost entirely black (typical *berinda*), but even the rare ♀♀ with somewhat more white markings have always still smaller spots on the underside of the hindwing than Sikkim ♀♀. According to Elwes the habits of *berinda* are entirely different from those of *ithiela*. They fly in Assam at 4—6500 ft. on sunny days round the tops of trees, only making short excursions into the surrounding open country, to return again to the shelter of the woods. The butterflies are not shy, have a slow and graceful flight and rest on Evonymus and scabious flowers. — In Burma, thanks to the drier climate, we again meet with a very light form, which earlier authors consequently *perspicua.* determined as *sanaca Moore*, the size of which approaches that of the Chinese *patrua Leech*, = **perspicua** *subsp. nov.* (56 a). ♂ with more extended yellow border at the inner margin and larger white discal spots on the hindwing, which, however, are never so extended as in *sanaca*. ♀ with white-dusted cell to the hindwing. Upper Burma. — *patrua Leech* (see vol. I, 19 c) is the oldest name for the most variable of the known *Delias*. As a lighter form, broadly striped with white, *lativitta Leech* (vol. I, 19 d) may be placed next to it. — Besides these forms which are indigenous to China only, there also occur in China analogies to the Indian varieties of *belladonna*, *zelima.* of which the one most resembling *perspicua* has been called **zelima** *Mitis*. — *adelma Mitis* (vol. I, 19 c) is a dark *yedanula.* race, whilst *subnubila Leech* forms a transition to *lativitta*. — I give the name **yedanula** *subsp. nov.* to a hitherto

unnoticed local form from the Omi Shan, which, like *sanaca Moore* and *perspicua m.*, is characterised by a pure white cell and much widened discal stripes on the hindwing. The yellow stripes of the under surface similar to those of *adelma*, but with white edges. Larva on Loranthus. Pupa elongate, brown with black spots and white tip. Head with two-pointed process, sides with short, but pointed spines. — **chrysorrhoea** *Voll.* (56 d) is the only island race yet known, nearest to *perspicua*, without white cell on the hindwing and habitually very small. Rare on the highlands of Sumatra at elevations of 4—6000 ft. *chrysorrhoea.*

d. Hindwing with thin, long, yellow basal streak.

D. albertisi *Oberth.* (= discus *Honr.* ♀) is among the most notable species, which always occur singly. OBERTHÜR'S ♂-type has the upperside of the forewing entirely blackened, with only 5 small yellow submarginal spots. The proximal part of the hindwing above is yellowish, the distal part black-brown. On the under surface a large transcellular black spot is noticeable. Dutch New Guinea. — **neyi** *Ribbe* (54 b) represents the local race from British New Guinea, above with the exception of the apical spot completely white and beneath without the black median spot on the hindwing. The ♀ is still unknown. *albertisi.* *neyi.*

D. niepelti *Ribbe.* ♂ above white with broad, black distal margin. Forewing in the ♂ with 5 obliquely placed white subapical patches, which are yellow in the ♀; ♀ above throughout chrome-yellow, anal half of the hindwing with greenish tinge. The under surface alike in both sexes, base and subapical spots of the forewing orange-yellow, all the rest black. Hindwing with peculiar fine grey-yellow submarginal lines, from which 7 delicate grey stripes run out to the terminal margin. British New Guinea. *niepelti.*

D. meeki *R. & J.* Somewhat smaller than the preceding, above very similar, but the under surface of the ♂ with paler yellow, more sharply defined basal part to the forewing and the hindwing with a large, triangular, pure white costal spot. The ♀ has likewise straighter black distal margins and the white costal spot on the under surface of the hindwing is oblong. British New Guinea. *meeki.*

D. callima *R. & J.* (56 e), which is here figured for the first time, is above white with uniform, moderately broad, black distal margin to both wings. ♀ different, has the upper surface black with yellowish green basal part to both wings and a chrome-yellow median band in the disc of the forewing. Beneath this band is somewhat broader. The under surface of the hindwing as in the ♂, the red submarginal band varying in extent. *callima* is very similar to *bornemanni*, from which, however, it differs in the white basal stripe. British New Guinea. *callima.*

D. blanca *Fldr.* has the rounded wings in common with *battana*. above throughout black-grey. with lighter central area on both wings and with very distinct whitish submarginal patches. Only 2 ♂♂ are known, from North Luzon. — **apameia** *subsp. nov.*, of which only ♀♀ are known, with the submarginal spots blue-grey instead of whitish and placed further from the distal margin. The yellow discal region of the hindwing is more extended in North Philippine specimens. Mindanao, Davao; discovered by Dr. PLATEN — **nausicaa** *Fruhst.* (54 f). The upper surface is very similar to the figured under surface, only on the hindwing the basal region is less sharply defined and somewhat lighter. The submarginal spots of both wings indistinct and the yellow region more restricted than in *blanca*. Very rare, only the one pair in coll. FRUHSTORFER known, which WATERSTRADT found on the Kina Balu. *blanca.* *apameia.* *nausicaa.*

e. Under surface of the hindwing with large, red, pointed basal spot.

D. descombesi *Bdv.* (52 b). Described from Cochin China, where a darker race, particularly in the ♀, occurs than the Himalayan subspecies which passes under this name. Moreover, the distal margin and the submarginal band of the Indo-Chinese *descombesi* are more broadly black, but the white submarginal spots of the forewing in the ♀♀ much smaller, so that the *descombesi*-♀♀ approximate to **eranthos** *Fruhst.* (52 c), from the Malay Peninsula, which is characterised by almost entirely black forewing with obsolescent white markings. — As **leucacantha** *subsp. nov.* the Sikkim race is here introduced, of which the figured dry-season-form (52 b) is especially typical in the white instead of yellow marginal spots on the hindwing beneath and the much larger submarginal patches, especially also in the ♀♀. There are three forms of the ♀: the one figured, with broadly white-grey veins on the forewing and light yellow upper surface to the hindwing; ♀-f. **auriga** *form. nov.*, with almost black forewing with the veins very finely white, yellow submarginal spots and yellow hindwing; and ♀-f. **leucogaea** *form. nov.*, with black forewing but white spots and reddish white upper surface to the hindwing. All three ♀-forms occur in Sikkim, the last also in Assam. The butterflies are common in the whole region, fly all the year round, in Siam in January in enormous numbers, and adorn even the parks in the large towns, such as Bangkok and Saigon, with their bright colours and the dazzling white of the upperside, floating slowly underneath the shady trees in company with *Delias hyparete ciris*. Although natives of the plains they ascend in Burma to an altitude of 7000 ft. It is curious that the species does not occur on the large Sunda Islands; it is there replaced by *belisama* and *eumolpe*, but appears again quite unexpectedly on the lesser Sunda Islands. *descombesi.* *eranthos.* *leucacantha.* *auriga.* *leucogaea.*

D. oraia *Doh.*, from Sumbawa, Pura, ♂ above as *descombesi*, only with somewhat broader grey apex. The ♀ likewise resembles the ♀ of *descombesi* above, the cell of the hindwing is also dusted with black and the *oraia.*

submarginal distal margin sends out rays into the middle of the wing. The ♀♀ bear on the wing a certain resemblance to Danaids and *Pareronia valeria*-♀. The ♂♂ fly round high tree-tops and bamboo bushes, but come down from their aerial heights in the early morning hours and form an ornament to the landscape on account of their numbers, their majestic flight and their large snow-white wings. On Lombok they inhabit elevations of 1500—6000 ft. The larvae live in large colonies on various kinds of trees and the pupae after 2—4 weeks produce
lydia. the butterflies, which emerge early in the day. — **lydia** *Fruhst.* (52 d) is a local form with pointed yellow-white apical spots on the forewing and narrower black bands on the underside of the hindwing. The cell of the ♀♀ pale yellow without black dusting, the wings are more rounded, all the submarginal spots orange-yellow instead of light yellow, the distal margin of the hindwing more sharply defined. Taken by EVERETT on Flores in numbers
vasumitra. in November. — The race figured (52 d) as *oraia* I now call **vasumitra** *subsp. nov.* It differs from *oraia* in the darker colouring and the reduced submarginal spots of both wings. Lombok.

D. belisama, a characteristic butterfly of Java, where it occurs everywhere, is separated on the island itself into two geographical races and one alpine, shows a strong tendency to variation and occurs locally in enormous numbers. In the Tengger Mountains once in April whole rows of bamboo bushes along a bridle-path were covered with them and when the thicket was struck with the whip literal clouds of butterflies arose, which after fluttering about a little while settled again. In the mountains the ♀♀ are commonly taken feeding at the flowers of Cinchona (Peruvian bark tree), often in company with *Delias crithoë* and *Prioneris autothisbe*, a marvellously beautiful sight! The larva lives on a Dioscorea and is very common from December to February. The pupa
nakula. yellowish with brown dorsal projections. — **nakula** *Gr.-Sm.* (= vestalina *Stgr.*) is the smaller East Javan race, which is paler beneath in both sexes. The figured (52 d) ♂ belongs to an aberration with the upper surface of
auratilis. both wings yellowish instead of white (**auratilis** *form. nov.*); there is a rarer form with uniformly dark ochre-
atisha. yellow upper surface (**atisha** *form. nov.*) or with reddish tinge (**erubescens** *Stgr.*). The ♀ appears in two principal
erubescens. forms, forma **nakula** *Gr.-Sm.* (52 e) with dark yellow proximal part (rainy-seasonform) and **yogini** *form. nov.*
yogini. with whitish or light yellow basal part on the upper surface, white instead of yellow subapical strigae on the forewing and light lemon-yellow under surface to the hindwing (dry-seasonform). ♀♀ without red basal spot on the hind-
depicta. wing beneath (ab. **depicta** *ab. nov.*) are very rare. — The larger West Javan race, **belisama** *Cr.* (52 d), is less
belisama. liable to variation. It is especially common in the neighbourhood of Sukabumi at elevations of 2—3000 ft. —
aurantiaca. In the alpine localities of the volcanoes of East Java from 4—6000 ft. occurs **aurantiaca** *Doh.* (= belisar *Stgr.*), with brilliant orange-coloured upper surface, large cell-spot on the forewing, and also a handsome extended
angaja. orange-yellow tint at the base of the forewing beneath, whilst the West Javan mountain form, **angaja** *form. nov.*,
balina. differs from it in the whitish yellow tinge of the forewing beneath. — **balina** *Fruhst.* is a smaller race with broad light yellow hindwing without margins above and the apical border more deeply incised. The under surface of
glauce. the forewing is more extended white at the inner margin. Bali. — **glauce** *Btlr.* (52 e), described from Borneo, a strongly darkened, distinct subspecies of larger size with almost entirely black under surface to the forewing which bears only slight traces of white or yellow submarginal spots. The butterflies are commonly met with on the tablelands of Sumatra at the brilliant red flowers of Erythinaea (Dadap trees).

eumolpe. **D. eumolpe** *Gr.-Sm.* (53 b) is the representative of the *belisama* and *descombesi* group on Borneo, where as yet it has been found exclusively on the Kina Balu at an elevation of about 4000 ft., not being rare.

zebuda. **D. zebuda** *Hew.* (52 d), the representative of *descombesi* on Celebes, where it flies almost all the year round and ascends from the edges of the woods at the sea-coast to about 6000 ft. The species is distinguished from all its allies by having the wings pointed instead of rounded, the ♂ above white with the apex broadly powdered over with grey-black; the ♀ grey-brown with large white cell-spot. South, Central and North Celebes.

diaphana. **D. diaphana** *Semper.* ♂ above scarcely distinguishable from *descombesi*, but beneath entirely black with abnormally large cell-spot on the forewing and similarly large submarginal patches on both wings. ♀: upper surface of the forewing yellowish with black discocellular and black distal margin with yellow spots; hindwing white with whitish submarginal patches. The under surface with broad black postdiscal bands on both wings. A magnificent, large species, only found as yet in South-East Mindanao, where it is not rare.

D. aruna, one of the largest and most strikingly coloured species of the genus, inhabits the Papuan region and may be broken up into a series of well-defined local races, of which three are already known from the main
aruna. island of New Guinea. **aruna** *Bdv.* (52 c), from Dutch New Guinea, with light yellow basal region on the hind-
madala. wing above. — **madala** *Fruhst.* Distal margin narrower, the ground-colour above orange, whilst on the under surface the red costal and discal spot are considerably larger and hence the black distal margin is reduced. German New Guinea, where it is not common, always flying singly, mostly met with in July in open woods. The butterflies are fond of visiting the flowers of Jambosa, on which they have been found even at elevations of 1000 ft.
irma. (HAGEN). — **irma** *Fruhst.* (53 b) is the darkest known race; ♂ beneath almost entirely black, also above with broader margins than *inferna*. The upper surface of the ♀ is often still darker than in the figure. Milne Bay,

British New Guinea. — **inferna** *Btlr.* (53 a), from Australia, has also above in the ♀ no yellow transverse spot at the discocellular of the forewing, which, however, appears again beneath. Otherwise the butterflies are beneath very similar to *irma*. Queensland. — **rona** *Rothsch.* is a race from Ron in Geelvink Bay which is unknown to us. — **bajura** *Bdv.* (53 a), from the island of Waigeu, differs from the continental forms of the species in the pale yellow basal part of the hindwing above and the sharply defined and narrower white transverse spot before the cell of the forewing. The species is not very rare on Waigeu; it most nearly approaches **seriata** *Fruhst.*, from the North Moluccas, the ♂♂ of which bear above a row of 6 white strigae on the forewing and 3 small submarginal spots on the hindwing. Batjan, Obi. *inferna.* *rona.* *bajura.* *seriata.*

D. madetes *Godm. & Salv.* (53 a) is clearly proved by its under surface to belong to the *descombesi*-group and is one of the most attractive species of the genus. The upper surface of the ♂ resembles that of *aruna*. ♀ above black with the orange-coloured discocellular patch which also occurs in *aruna* and 6 whitish submarginal spots. The central part and the inner margin of the hindwing dirty yellowish white. The distal margin broadly black, enclosing 6 washed-out yellowish patches. New Mecklenburg. — **honrathi** *Mitis*, a distinct island race from New Pomerania, where it is very rare, is distinguished by the whitish instead of yellowish spots on the under surface, the likewise whitish strigae of the forewing and the reduced submarginal spots on the hindwing beneath. *madetes.* *honrathi.*

D. harpalyce *Don.* (53 c) belongs with the following species to the most ornamental *Delias*. The ♀ is above black with grey-brown base and a continuous row of 6—7 yellowish submarginal spots on the forewing. Mostly flies high, but congregates in the spring (beginning of October) round flowering fruit-trees and is then easy to catch (Seitz Ms.). South Australia, Victoria, New South Wales. *harpalyce.*

D. aganippe *Don.* (53 c), beneath for the most part black with white longitudinal bands and submarginal spots on the forewing, red submarginal patches proximally bordered with white and yellowish discal spots on the hindwing. Likewise in South Australia, but distributed northwards to Queensland. *aganippe.*

D. nigrina *F.* (53 c), with orange-yellow subapical spots on the forewing, which are somewhat lighter in the ♀, on a black ground, base of both wings grey-blue, hindwing with sinuous red submarginal and black median and terminal bands. Flies even in the winter (June), when there are scarcely any other butterflies in South Australia. The ♂♂ appear entirely white when flying, as somewhat singularly hardly anything of the bright under surface is visible; only when the butterfly drops down onto a flower from the height at which it mostly flies, and in so doing closes the wings, the beautiful under surface becomes distinct (Seitz Ms.). *nigrina.*

D. splendida *Rothsch.*, above similar to *descombesi* and *oraia m.*, with narrower, but deep black, distal margin to the forewing. The underside of the forewing is entirely black, with a black spot at the end of the cell, the apical patches orange-yellow, the hindwing similarly coloured, only bearing 5 rudimentary submarginal spots. ♀: upper surface black, with large light yellow submarginal spots on both wings, large yellowish cell-spot on the forewing and yellowish basal area on the hindwing. A distinct species, only known from Timor, where it was discovered by Doherty. *splendida.*

f. Under surface of the hindwing with segment-like, red basal spot.

D. aglaia is the first-known representative of a group, the species of which as a rule occur in great abundance, are mostly found in the plains, and even venture onto the sea. There are only a few mountain species, which do not descend below 4000 ft. Larvae red, each segment with long hairs, of which the lateral ones are black and the dorsal yellow. On young leaves of Nauclea rotundifolia, where they rest close together in large numbers. Pupa blackish, as in the other species with dorsal points. — **curasena** *Fruhst.* ♂ black with yellow inner margin to the hindwing and with blue-grey stripes and spots on both wings. ♀ similar to that of *grisea* (56 c), but with the upper surface somewhat lighter. ♂ beneath with yellow hindwing, which is intersected by broad black vein-stripes connected by transverse streaks. Formosa. — **porsenna** *Cr.* Somewhat larger than the preceding, ♀ with yellow median band on the forewing beneath. South China, Hong-Kong, Hainan (?). — **tonkiniana** *Fruhst.* Smaller than the preceding and the ♀ with finer stripes. Median band of the forewing beneath yellowish, the upper surface darker than in specimens from Northern India. Tonkin. Found in the rainy season. — **thyra** *Fruhst.* (56 c), in both sexes the albinotic extreme of the preceding. Forewing of the ♂♂ more extended blue-grey. Hindwing of the ♀♀ in many examples almost pure white. Annam, Siam. Only taken in the dry season. — **beata** *Fruhst.* is the race from the Mergui Archipelago and South Tenasserim, a connecting link between Indian and Sumatran specimens. ♀ with yellowish cell-spot on the forewing above — **aglaia** *L.* (= pasithoë *L.*, dione *Don.*), one of the commonest Indian species, occurring from Nepal to Assam and Upper Burma, especially in the hot valleys and except in the cool January very abundant. Visits flowers. Ascends in the Shan States to 5000 ft. ♀ of the rainy-season-form with grey-black, that of the dry-season-form with whitish median band on the forewing. ♀ very variable, every specimen different. — **parthenope** *Wall.* (= distanti *Stgr.*). A very interesting, rare form. ♂: forewing with pointed, long grey patches, ♀ with almost white median band occupying a third of the wing. Malay Peninsula, Singapore. — **goda** *Fruhst.* (56 b) is the race from Sumatra, which mostly *eurasena.* *porsenna.* *tonkiniana.* *thyra.* *beata.* *aglaia.* *parthenope.* *goda.*

keeps to the mangrove thickets at the shore. ♂: forewing almost without grey strigae, with strongly darkened, blue-grey median spot. ♀ darker than that of *parthenope*, with dark instead of pale yellow under surface to the
grisea. forewing. — In **grisea** *Fruhst.* (56 c), from Nias, the melanotic differentiation has progressed furthest. The grey median spots of the forewing reduced to a narrow band at the submedian, hindwing without a trace of yellow, ♀ with the upperside of the hindwing entirely brown-black and beneath with the yellow interneural areas restricted
pandecta. by the widened black veins. — **pandecta** *Stgr.* is a similar race, but the ♀ has still traces of a yellow median band on the forewing and in the ♂♂ the inner margin of the hindwing above is broadly spotted with yellow. Palawan, North Borneo (?).

pandemia. **D. pandemia** *Wall.* (56 b), an interesting transitional form, which connects *aglaia* with *egialea* by the intensively dark canary-yellow anal spot on the hindwing, which in the ♀ enters the cell. The ♂♂ with blue-grey strigae on the forewing as in *aglaia*. North Borneo, Palawan.

thysbe. **D. thysbe.** Distinguished by the fact that the under surface also bears a broad, intensively red basal spot. CRAMER'S subspecies **thysbe** is described from China and probably also just this form occurs in Tonkin. But
pyramus. the form best known as one of the commonest Himalayan butterflies is **pyramus** *Wall.* (56 a), distributed from Nepal to Burma and the Malay Peninsula. In the deeper valleys in Sikkim the species is common from April to December and has even been observed in Burma at an elevation of about 1000 m. The ♀ is similar to that of *alluviorum*, it has, however, also grey in the cell of the forewing, but the hindwing less tinged with yellow. —
kandha. **kandha** *Doh.*, taken at 3—3500 ft. in the Madras Presidency of South India, is distinguished by a pale yellow subbasal part on the upper surface and lighter and more lemon instead of ochre-yellow colour on the underside of the hindwing.

ninus. **D. ninus** *Wall.* Smaller than *pyramus* with blue-grey instead of black colour on the upper surface and
alluviorum. narrowed, black subbasal band on the hindwing beneath. Malay Peninsula. — **alluviorum** *Fruhst.* (56 a), somewhat larger with more extended red basal spot and much broader black subbasal band on the hindwing beneath.
parthenia. Sumatra. — **parthenia** *Stgr.*, a distinct island race with broader black margins to both wings and light yellow discal region on the hindwing. Rare on the Kina Balu, North Borneo.

D. crithoë, an ornament of the Javan timber-forests, which we meet with everywhere where there are plantations at elevations of over 4000 ft. The butterflies are especially attracted by the flowers of Cinchona ledgeriana, at which they feed, hanging on them with the wings closed, and are commonly found in company with *Prioneris autothisbe*, which is similarly coloured beneath, a striking sight, as the yellow and red hindwing
bromo. stands out so sharply against the dark green of its surroundings. We have to enumerate five local races: **bromo** *Fruhst.* (= dymas *Nicév.*) (56 c), from East Java, where it is principally found on the volcano Bromo and in
crithoë. the Tengger Mountains. — **crithoë** *Bdv.*, from West Java, with darker forewing, which in the principal form has only a slight blue-grey discal dusting, hindwing in both sexes much more broadly margined with black. Very
fastosa. variable, no two specimens are identical. — **fastosa** *form. nov.* has in the ♀ a broad grey-blue transverse band recalling *henningia*, which extends from the costal margin through the cell and terminates at the median of the
funesta. hindwing. — **funesta** *form. nov.*, with the forewing in both sexes entirely black without grey discal dusting. I found this form on the plateau of Pengalengang, 4000 ft. high, at that time still covered with dense woods, in the interior
chrysendeta. of the Preanger Residency of West Java. — **chrysendeta** *subsp. nov.*, with narrower black distal margin than *bromo* and with the hindwing tinged with darker orange-colour. Mount Haruhasa on Sumbawa. In coll. OBER-
tobahana. THÜR. — **tobahana** *Rogenh.* (= derceto *Nicév*). Larger than *crithoë*, the red basal spot of the hindwing not showing
villia. through above. Discovered at Lake Toba, North-East Sumatra. — **villia** *subsp. nov.* (56 a), a local race from the Padang Bovenlanden in West Sumatra, with pure white instead of yellowish subanal region on the hindwing, which is distally densely powdered with blackish, and more sharply defined white crescents on the forewing.

egialea. **D. egialea** *Cr.* (56 b), a species showing striking sexual dimorphism, very local on Java, on the other hand abundant in the dry season on the island of Bawean. Under surface of the forewing of the ♂♂ with very broad, almost pure white median area, which in the ♀♀ is dark yellow. Is also recorded from Banka, Billiton and Sumatra by VOLLENHOVEN. Larva chestnut-brown with darker head and first segment, and with a yellow transverse band on the following segments, which are adorned with some long yellow hairs.

henningia. **D. henningia** *Ersch.* (56 b), a very variable species. ♂ above with broad blue proximal half to the forewing and large, blue-grey costal area on the hindwing. Forewing without grey subapical strigae. ♂ beneath with 2 subbasal yellow patches in and above the cell and relatively large spot at the apex of the cell. An accidental
ochreopicta. hemera. or seasonal form with darker orange spots has been described by BUTLER as **ochreopicta.** Luzon. — **hemera** *subsp. nov.* is a darkened island race, probably from Mindoro, with black basal area on the forewing above, almost without the blue-grey tinge at the costa and with smaller, dark orange-coloured anal spot on the hindwing. Under surface: white median of the forewing narrower; hindwing: red basal spot shorter, all the black markings extended, the yellow patches beyond the cell reduced to minute dots. The orange-coloured submarginal region strongly nar-

rowed. — **voconia** *subsp. nov.*, from Bohol, very similar to the preceding, but with the blue median area on both surfaces of the forewing in ♂♂ and ♀♀ even less developed. — **camotana** *subsp. nov.*, with pure white, relatively broad median band on the forewing, from Camotes, forms a transition to **ottonia** *Semp.*, of which the ♂♂ are distinguished by the dark blue-grey, more sharply defined median area of the forewing and the ♀♀ by the pure white median band of the forewing and by the median spot on the underside of the hindwing filling up almost the whole of the cell. Mindanao. — **lucerna** *Btlr.*, with the uncertain locality Mindanao, is the name of a local or seasonal form with the median bands on the forewing even narrower than in *hemera* and *henningia* and pure white in the cell. — **saturnia** *form.* (or *subsp.*) *nov.* differs especially on the hindwing beneath in the stronger development of the black basal spots, in consequence of which the yellow patches in and around the cell and also the submarginal area are reduced. East Mindanao. *voconia. camotana. ottonia. lucerna. saturnia.*

D. kummeri *Ribbe* (54 c). ♂: above pure white with the broad black apical border which is typical of so many New Guinea *Delias*, which in the ♀ is also continued on the hindwing. Forewing of the ♀♀ somewhat shorter than in the ♂♂. — An interesting form, in which the red submarginal line of the hindwing beneath is continued from the anal angle to the costal margin, has been named by Rothschild and Jordan **ligata** (56 f). Locality the Aroa River, British New Guinea. *kummeri. ligata.*

D. weiskei *Ribbe* (= mirifica *Gr.-Sm.*) (56 f). Above like the preceding. The ♀ has likewise a broader black distal margin and 2 or 3 white subapical dots on the forewing, which are absent in the ♂. Locality as the preceding. *weiskei.*

D. bornemanni *Ribbe* (56 e). The upper surface in both sexes as in the preceding except that the black distal border of the forewing is widened to beyond the margin of the cell. On the under surface the red spots are somewhat reduced in the ♀. British New Guinea. Common. *bornemanni.*

D. microsticha *R. & J.* (56 e). This species belongs to the *mysa*-group according to the character of the pattern of the under surface, but is included here on account of having the basal spot of the hindwing beneath red instead of yellow. The ♀ is still unknown. British New Guinea. *microsticha.*

6. Genus: **Prioneris** *Wall.*

The species of this genus, which is distinguished by the dentate costal margin of the forewing in the ♂♂, approach *Delias* in their habitus and the character of the markings. But the butterflies are altogether more robust and are more rapid fliers than the *Delias*. Forewing with four subcostal veins, of which two arise before the end of the cell, as in *Pieris*. The genus differs from the likewise allied *Tachyris* by the absence of the anal tufts of hair. Larvae blue-green, laterally adorned with soft white hairs and with blue tubercles, those at the head and sides with black dots. On Capparis. Pupa light green, head with sharp tip, the dorsum keeled with a yellow line, laterally armed with 2 strong spines. Butterflies on the mainland of India in the warmer valleys, but in the Malay Archipelago preeminently inhabitants of the mountains. Some species rare, but sometimes occurring in many thousands. The very resistant dentitions of the forewing, with the points directed towards the apex, can easily be recognised even with the naked eye. The small, close teeth are so strong that they are capable of catching the finger and causing the wing to bend when the tip of the finger is moved along from the apex to the base. Wallace regards the „rarer" *Prioneris* as a mimetic form of the „commoner" *Delias*. But I cannot accept his view, since mimicry among the in all respects harmless Pierids appears no sort of protection, and properly speaking the smooth-margined *Delias* should rather copy the armed *Prioneris*, if there is assumed to be mimicry at all.

P. thestylis *Dbl.* (57 e), a characteristic butterfly of the Indian fauna, distinguished by its size and its tendency to horodimorphic variations. The under surface of the rainy-season-form black, with large white spots on the forewing and long, light to dark yellow patches and similarly coloured cell on the hindwing. — The ♀♀ of the rainy-season-form, **seta** *Moore*, are also beneath predominantly black, with narrow yellow cell-stripe and reduced submarginal spots on the hindwing beneath. The dry-season-form, **watsoni** *Hew.* (57 a), to which many transitional forms lead over, is beneath tinged with black only at the apex, at the costal margin of the otherwise white forewing and round the cell of the otherwise light orange-yellow hindwing. Only the under surface of the forewing of the ♀ is entirely black like that of the rainy-season-form. The *thestylis* are fond of open country; they fly high and jerkily and congregate at sand-banks or moist places, sometimes to the number of many hundreds. The ♀, however, exclusively visits flowers. In the Himalayas the butterflies ascend to 5000 ft. — The Sikkim form is somewhat lighter than the melanotic specimens from Assam. *thestylis* has also been observed recently in the West Himalayas. — **jugurtha** *subsp. nov.* is a larger race with more extended white subapical and sub- *thestylis. seta. watsoni. jugurtha.*

marginal spots on the underside of both wings and also in the rainy-season-form with light sulphur-yellow under
malaccana. surface to the hindwing. Siam, Tenasserim, Tonkin, Annam. — **malaccana** *Fruhst.* (57 b), a smaller, strongly darkened local form from the Malay Peninsula, in which, however, the cell of the hindwing beneath is only quite narrowly bordered with black. Of the ♀ only one specimen in OBERTHÜR'S collection is known, smaller than *seta*-♀ from Sikkim: hindwing with very narrow black distal margin, otherwise almost entirely orange-coloured. —
hainanensis. **hainanensis** *subsp. nov.* is in size a still less developed island race with lighter yellow hindwing in the rainy-season-
mamilia. form also. **mamilia** *form. nov.*, the dry-season-form of the preceding, in contrast to Sikkim specimens, has also
formosana. in the ♂♂ the cell of the forewing beneath entirely tinged with black. Hainan. — **formosana** *Fruhst.* Upper surface yellowish instead of white, the black markings of the forewing reduced, hence the subapical spots extended. Under surface: apex of the forewing more broadly suffused with greenish yellow. Hindwing with much larger light canary-yellow spots than in Indian *thestylis*. Formosa, at elevations of 4000 ft. at Lake Lehiku and near Chip-chip, in June-July very common.

cornelia. **P. cornelia** *Vollenh.* (57 d), belonging to the *thestylis*-group on account of the absence of the red basal spot on the underside of the hindwing, is a mountain species. The veins on the under surface are finely edged with grey; hindwing dark yellow with grey costal and rarely also median antemarginal spots, without any white postdiscal tinge. North Borneo.

sita. **P. sita** *Fldr.* Above white with black veins, beneath very similar to *Delias eucharis*, but with quadrate instead of roundish red submarginal spots on the hindwing beneath and yellow instead of white apex to the forewing. *sita* flies always in company with *eucharis*, of which it is considered a mimic, rests just like the latter on the red flowers of the Lantana with closed wings, but may be distinguished by the more jerky, rapid flight. ♀ similar to the ♂, only with black transverse lines between the veins of the hindwing. Ceylon, South India, ascending to 5000 ft., rare. Flies in January. Larva on Capparis tenera according to BELL and GREEN.

autothisbe. With **P. autothisbe** *Hbn.* begins the series of species with red basal spot on the hindwing beneath. Two forms of the ♀ occur, one with almost entirely black forewing and the other with 3 large whitish discal patches
albiplaga. orientalis. on the forewing: **albiplaga** *form. nov.* (57 c). West Java. — **orientalis** *Fruhst.* (57 c) is a smaller race with narrower black border, especially on the hindwing, and as a rule with the apical part of the forewing more plentifully dotted with white. The under surface of the hindwing is lighter yellow, the black submarginal bands weaker.
albifera. Specimens also occur with entirely white under surface (**albifera** *form. nov.*) and more commonly examples with
mucida. the upper surface of the hindwing completely dusted with grey-brown even in the cell (**mucida** *form. nov.*). The latter form occurs also in West Java, but there, in accordance with the darker general colouring of typical *autothisbe*, this dusting is almost deep black and is interrupted by large yellow and grey submarginal spots. — *autothisbe* is a mountain species, which inhabits exclusively altitudes of between 4000 and 6000 ft., but is distributed over the whole island. I observed these *Prioneris* most commonly on the Tengger Mountains, at the volcano Gedé and near Bandong, where they visit the sweet-scented flowers of the Cinchona (Peruvian bark) trees, always in company with the similarly coloured *Delias crithoë*, and fly all the year round. They are apparently most abundant in the months of June and July, during the dry season, when these companions can occasionally be surprised drinking at moist places.

hypsipyle. **P. hypsipyle** *Weym.* (67 c) differs from the preceding in the entirely black under surface of the forewing and the absence of the red cell-spot on the hindwing. The very rare ♀ is very similar to the ♂, with only slightly broader black margins to the roundish wings. Mountains and highlands above 4000 ft. Sumatra, on damp river-banks sometimes in hundreds.

philonome. **P. philonome** *Bdv.* (57 a), with white under surface to the forewing and light-yellow tinted hindwing, which is traversed by a relatively broad black submarginal band. Only known from East Java, where I met with it near Lawang at about 2000 ft.; it is not very rare, especially in April, and is fond of visiting flowers at the edges of fields and roads. Of the ♀♀ I found 3 forms: similar to the ♂, with yellowish white upper surface to
herennica. both wings, another with greenish yellow upper surface (*form.* **herennica**) and a very rare form with blue-white
lactaria. upperside (= **lactaria** *form. nov.*). Of the ♂♂ a form with white instead of yellow basal part and white cell on
nivescens. the hindwing deserves mention (= **nivescens** *form. nov.*).

vollenhovi. **P. vollenhovi** *Wall.* (57 d). Apex of the forewing more pointed than in the preceding; distal border of the upper surface more broken up. Hindwing dark yellow with black anal tinge and white spots round the cell on the under surface. Only known from Borneo, where it replaces *philonome*.

clemanthe. **P. clemanthe** *Dbl.* (57 b, d), beneath with chrome-yellow hindwing, which anally is somewhat darker. Under surface of the forewing in the ♀ black, that of the hindwing entirely yellow, whilst the ♂♂ have a white distal margin. Rare in Sikkim, common in Assam; a frequenter of flowers, fond of the open country and

the edges of woods. — **helferi** *Fldr.* is a darker local race, in which the veins on the underside of the forewing are connected by distinct black transverse bands. Ascends in Burma to a height of 7000 ft. Tenasserim, Tonkin, Siam, Shan States. — **saenia** *form. nov.* is a smaller, lighter race or seasonal form, without a trace of a submarginal band and with a lighter yellow basal tinge on the hindwing; South Annam, January, February. — **euclemanthe** *Fruhst.* Hindwing beneath light lemon-yellow, without a trace of darker colour in the anal area. Colouring of the veins on the upper surface of the forewing much thinner than in continental specimens; Hainan. — **themana** *Fruhst.* (57 b), on the contrary, has the veins broadly striped with black, a darker apical and anal tinge on both wings and a more extended white area on the hindwing beneath. Sumatra, Malay Peninsula.

helferi. *saenia.* *euclemanthe.* *themana.*

7. Genus: **Anaphaeis** *Hbn.*

This well-defined genus is always united with the African *Belenois Hbn.*, which contains only one species. *Anaphaeis* differs from *Huphina* in having the subcostal veins which arise before the apex of the cell united (anastomosing) at their distal extremity with the costal, and the middle discocellular much longer, but still always shorter than the lower discocellular. From *Belenois*, however, *Anaphaeis* is distinguished by the shorter middle discocellular of the forewing.

The few species are almost of the same size; they occur abundantly, often congregate in great numbers and are of migratory habit. One species is so to speak always on the way betweeen Africa and India (*mesentina*) and in Kashmir and Palestine enters the Palaearctic Region. Larva on Capparideae; pupa pointed, with lateral spines.

A. mesentina *Cr.* Dealt with in the Palaearctic part (vol. I, p. 50, pl. 21 d, e). Two seasonal forms of this variable species have been named: **lordaca** *Wlkr.*, beneath pale yellow, that of the dry season, and **aurigena** *Btlr.*, beneath dark to orange-yellow, that of the rainy season. Although inhabiting the hot lowlands, the species commonly ascends to 6 and 8000 ft., and has been sporadically found even at elevations of 3000 m., perhaps carried up by the wind. Eggs in clusters, larva always gregarious on Capparis. Baluchistan to Sikkim, once also met with on the Nicobars. — **taprobana** *Moore* (= fervidior *Fruhst.*) (63 f) is above more broadly black and beneath a magnificent orange-yellow. A slow flier; is fond of resting on the ground. Time of appearance uncertain; sometimes only twice in the course of five years; but when they occur they unite in migratory swarms. In June, July and then again in November, December.

mesentina. *lordaca.* *aurigena.* *taprobana.*

A. java *Sparrm.* (63 d), a variable species, which is distributed as far as the Fiji Islands, appears everywhere in two seasonal forms, and in Australia under varying climatic influences is divided into a number of forms described as separate species. The butterflies are sluggish, fluttering slowly and heavily from flower to flower and are often seen resting together in hundreds, immediately after emergence, in the thick bushes at the edges of the woods. On Java they do not ascend above 2000 ft., but in Lombok I met with them in large numbers on the flowery plateau of Sambalun at 4000 ft., MARTIN has found the larva on Celebes. On Java itself there are two seasonal forms: ♀ with grey-violet base to the forewing above and black distal margin extending to beyond the middle of the cell (rainy-season-form); — and **coronea** *Cr.*, ♀ with half the wing white, distal margin only extended to the apex of the cell. On the under surface no special variations are noticeable in specimens from Java to Sumbawa. But the further we go towards the east, the more marked becomes the influence of the dry season, which sometimes lasts for nine months. On Sumba the black distal margin of the forewing already begins to become narrow, so that the black spot at the apex of the cell stands separate (**magniplaga** *Fruhst.*). The base of the under surface of the forewing in the ♀ is yellow instead of dark ochre-colour; the cell of the hindwing white. — On the island of Savu occurs next a specialised race, = **savuana** *Fruhst.* (63 e). The black distal margin is reduced also in the ♀♀ and on the hindwing leaves the black transverse spot in the cell isolated; the forewing remains ochre-coloured only in the cell; the costal area remains white and the hindwing bears a row of white spots round the cell. — **ina** *Fruhst.* is the race from Kisser and Babber, with the upper surface of both wings still lighter, a less yellow tint on the under surface and white cell to the hindwing. Some ♂♂ already approach *teutonia* in having the hindwing entirely white with the exception of the black distal margin. — **anita** *Fruhst.* (63 d) is an intermediate form, from the island of Wetter, with the basal area of the under surface in the ♀♀ tinged with yellow. — **teutonia** *F.* is the Australian race of the species, which has found its way from this continent as far as Java. The principal form is figured at 63 f; together with it there occur also ♀♀ with black distal margin to the upper surface, which only bears small white submarginal spots or none at all, and whose base is yellowish instead of white (♀-f. **clytie** *Don.*). A still more melanotic summer form on both surfaces is **peristhene** *Bdv.* (63 f), with the hindwing entirely black beneath. — **niseia** *Mc. Leay* (63 e) is a very beautiful intermediate form with the veins on the hindwing above broadly striped with black and long white circumcellular areas on each side of the likewise white cell, which form a pleasing contrast to the black ground. — Egg light straw-yellow, larva on Capparis lasiantha; cylindrical, narrowed at both ends. Head black, with a V-shaped spot on the frons, otherwise olive-brown sprinkled over with small yellow dots, venter yellow-green. When full-grown the larva spins itself up on a leaf and changes within 24 hours into a green, somewhat angular pupa. The butterflies fly

java. *coronea.* *magniplaga.* *savuana.* *ina.* *anita.* *teutonia.* *clytie.* *peristhene.* *niseia.*

picata. swiftly, often rest on flowers, and gather together for large migrations across the sea. — **picata** *Btlr.* (63 e) is a race which is chiefly white also beneath, with thin black bands and vein-stripes on the under surface; Bis-
micronesia. marck Archipelago. — **micronesia** *Fruhst.* (63 e) is the subspecies from the Fiji Islands which is adorned with
vitiensis. dark orange-coloured submarginal spots beneath; of this **vitiensis** *Fruhst.*, analagous to *peristhene*, represents
clarissa. the darkest seasonal form and **clarissa** *Btlr.* an aberration corresponding to *nisea*, with handsome light yellow submarginal-patches on the hindwing beneath.

8. Genus: **Baltia** *Moore.*

In the short, club-shaped antennae the few species of this genus approximate to *Synchloë* and *Euchloë*; the course of the subcostal veins associates it with *Huphina*, but the genus is completely isolated through the absence of the middle discocellular. The radial veins arise from the subcostal. *Baltia* approaches *Aporia* in the shape of the scales, which are roundish, broader than long. All the species are high-alpine and inhabit altitudes of 4500—5500 m., which are already destitute of all vegetation. There they fly near the ground, except when they play in the sun or run with half-opened wings over the sandy soil, thus sometimes traversing long distances and, if disturbed, quickly hiding among the inequalities of the ground.

butleri. **B. butleri** *Moore* (vol. I, 23 b). ♂ beneath with fine brown longitudinal stripes at both sides of the veins. Ladak. Kashmir, Karakorum, at altitudes of 15—18000 ft.

shawi. **B. shawi** *Bates* (vol. I, 23 b). Rarer than the preceding, under surface of the hindwing grey-violet with black vein-stripes. North-West Himalayas, Kashmir, Karakorum.

sikkima. **B. sikkima** *Fruhst.* (50 e). Differs from the preceding species in the submarginal band, which also in the ♂ traverses the entire forewing and is continued on the hindwing. Under surface brighter than in the other known species; apex of the forewing and the whole hindwing traversed by long yellow stripes; cell likewise yellow instead of white. Kamba-jong (South Tibet), at the border of Sikkim, reported from elevations of 12—16000 ft.

9. Genus: **Aporia** *Hbn.*

The typical representatives of this genus do not differ essentially in neuration from *Pieris s. str.*, nevertheless their habitus is entirely different. The membrane of the wing is stiffer, resembling paper; in the ♀♀ the scales are partly absent, leaving transparent places, and the flight is altogether distinct from that of the other Pierids, more resembling that of the Parnassiids. That is to say, whilst the other Pierids move forwards by striking the wings up and down, *Aporia* commonly holds the wings stiff and immoveable, using them like a parachute. The position of the second subcostal vein varies somewhat; it often arises from the upper angle of the cell, or at a short distance before the angle. The untenable genus *Metaporia* has been based on the latter character. If, however, this is allowed to stand, then the genus *Aporia* only contains 2 species (*crataegi* and *soracta*), all the others, as well as *hippia* for instance among the Palaearctics, must be united with *Metaporia*. Here, however, no importance is attached to this criterion and all the species are regarded as belonging to the homogeneous genus *Aporia*. In any case *Aporia* represents phylogenetically a very old stirps, a sort of connecting link between the Pierids and the Parnassiids. With the latter they have in common the short palpi and the circular scales of the costal region. The Asiatic species, with the exception of *agathon*, only vary moderately, and are almost exclusively inhabitants of high alpine regions, being often very abundant locally, but in the large majority of cases are among the rarer species.

The larvae live gregariously under a fine web on Prunaceae and Rubiaceae, are usually of a green or red-brown colour and adorned with fine, soft hairs.

A. soracta. Occurs in the West Himalayas sometimes in great abundance, but only for a short time, in April and May, never frequents gardens or open country, but only the edges of woods, 6—9000 ft. is its favourite zone, but in Kashmir it also ascends to 14000 ft. The elongate brown larva ornamented with fine, soft hairs; pupa with obtuse horn on the head, a thoracic and an abdominal protuberance, white covered with black dots.
soracta. On Berberis lycium. Two local races deserve mention: **soracta** *Moore* (vol. I, 18 a), with broad black subapical
denigrata. and cell-band on the forewing, from Mussourie; — and **denigrata** *subsp. nov.*, forewing almost pure white, either without or with only very weak black lines. Punjaub, North-West Provinces.

balucha. **A. balucha** *Marsh.* (= sorex *Gr.-Sm.*, leechi *Moore*). Local form of *leucodice Eversm.* (vol. I, 19 a), from Turkestan, from which it differs in the broader black bands on both wings and the distinct orange-coloured stripes at the costal margin and the darker yellow under surface of the hindwing. Baluchistan.

A. nabellica *Bdv.* (vol. I, 19 b) is an interesting Pierid, above black, on the underside of the hindwing dark yellow. I have it from Mardan in the North-West Provinces and it is also known from Kashmir and Kunawur,

where it occurs at elevations of 9—13000 ft., flies slowly and heavily and is fond of settling on Umbelliferae, which tower above the thick masses of flowers that ornament the clearings in the wooded mountain glens (Lang). Specimens from Kashmir are lighter than those from Kunawur.

A. harrietae *Nicév.*, an interesting, highly specialised local form of *larraldei Oberth.* (vol. I, 18 d), and distinguished from it by a complete, concave row of white oblong transcellular spots on the forewing and predominantly white-yellow under surface to the hindwing. Very local, hitherto only known in a few specimens from Bhotan. *harrietae.*

A. larraldei f. **nutans** *Oberth.*, unknown to me in nature. Occurs in Yunnan.*) *nutans.*

A. genestieri *Oberth.* (57 a) approaches *bieti Oberth.* (vol. I, 17 c), but the distal margin of both wings is more extended smoke-brown. *genestieri.*

A. hastata *Oberth.* is a very large species resembling *larraldei*, with 3 large, white submarginal spots in the middle of the black distal region of the forewing. Hindwing white with a few black submarginal streaks. Yunnan. *hastata.*

A. agathon, which is the most variable species of the genus, is broken up into several local races and moreover varies strongly individually. **agathon** *Gray* was described from Nepal, is very rare there and in Sikkim, but very common in Assam, in North Yunnan (Tse-kou) at about 2000 m. It is above predominantly black with broader grey stripes in and below the cell and two rows of whitish spots in the submarginal region of both wings. Hindwing beneath with large, round, yellow basal spot. — **phryxe** *Bdv.* (vol. I, 19 a) is the lightest extreme of the species and the subspecies of the West Himalayas, known from Simla, Kangra, Kashmir and Tibet. Ground-colour white with black vein-stripes, which are sometimes widened so as to form reticulate markings (f. **caphusa** *Moore*). When these reticulations are still more thickened they suppress the white ground-colour, and a form is produced which is only a little lighter than the East Himalayan *agathon*. The latter form is **ariaca** *Moore*. — The species has recently been discovered also in Formosa at 8000 ft. and described as **moltrechti** *Oberth.* — Larva on Berberis nepalensis, gregarious, dirty brown, head black, dorsally with dark brown stripes, sparsely adorned with soft white hairs. Before pupation the colour changes into a light green. They make a thick web and then lie up to the number of 10 or more in one web. But for pupation they go under the dry leaves of their food-plant. Pupa like that of *soracta*, but greenish yellow with black spots. *agathon. phryxe. caphusa. ariaca. moltrechti.*

10. Genus: **Pieris** *Schrk.*

This group contains the species which have been longest known, some of which are distributed over three-quarters of the world and in some places are well known and feared on account of their great abundance and the damage they cause. The principal characteristic is the oblique middle discocellular of the forewing, which is only half as long as the concave lower discocellular. The precostal of the hindwing always curved distad.

P. brassicae. L. is distributed everywhere in India, from Afghanistan to Sikkim, Bhotan and South Tibet, where cabbage is grown in gardens. It is there abundant at alpine heights of 10,000 ft., and has even been repeatedly taken at 17,000 ft. The Indian subspecies has been designated **nepalensis** *Gray* (vol. I, 17 e), and occurs, as with us, in two generations. The rainy-season-form differs essentially from the European race in the more broadly black apex and the darker yellow under surface of the hindwing. Specimens of the dry season, from Kashmir, are scarcely distinguishable from those from Smyrna and Rome. *nepalensis.*

P. deota *Nicév.* (vol. I, 20 a), distributed from Kashmir to the Lob-Nor and Pamir, is distinguished by the uniform black distal margin of both wings, which is deeply dentate proximally, and the peculiar blue-grey tinge of the under surface. The species inhabits desolate plateaux, only sparsely overgrown with Carex and Astragalus, where it occurs quite singly, is very rare and usually flies swiftly. *deota.*

P. canidia *Sparr.* (vol. I, 20 b), a variable butterfly, which occurs all the year round, ascends from the plains to 12,000 ft., always remains in the neighbourhood of gardens and in Tonkin even flies about on the grass-plots before the hotels in the town of Langson. There occur specimens without black discal spots on the forewing (f. **claripennis** *Btlr.*), others with yellowish under surface and small black discal patches on both wings (f. **gliciria** *Cr.*), ♂♀ scaled with dark grey or yellowish above (f. **sordida** *Btlr.*). I possess a winter brood (Novbr.) from China with grey-black under surface to the hindwing. Luzon examples bear beneath broad black-grey streaks, Tonkin specimens of June and July are the lightest, being beneath pure white. The species is distributed from the North-West Himalayas to Hainan, Formosa and the Loo Choo Islands. — A very small race from Tibet has *canidia. claripennis. gliciria. sordida.*

*) According to the figure in Oberth., Ét. d'Ent. 16, pl. I, fig. 3, it is distinguished above from *A. phryxe* (vol. I, pl. 19 a) by much more black-brown, which forms an irregular submarginal band on both wings and is confluent with the oblique discocellular band on the forewing.

minima. been named **minima** by VERITY. South Indian specimens are especially strongly spotted with black. — Pupa yellowish brown with projecting wing-cases, laterally on the abdomen some dark brown points.

naganum. **P. naganum** *Moore*, from the Naga Hills in Assam and Upper Burma, has only been brought to Europe as yet in two specimens. Upper surface pale yellowish white, apical spot of the forewing as in *brassicae*, at the end of the cell a black spot, another spot as in *canidia* between the anterior median veins. Hindwing above white, beneath pale yellow. Forewing with pale yellow apex and the two black spots of the upper surface reproduced.

rapae. **P. rapae** *L.* (vol. I, 29 c), distributed from Afghanistan to Kashmir in the Indian region and not rare at altitudes of 7—12,000 ft., occurs in a form which most nearly approaches the European *metra Steph.* and is noteworthy for the finely divided apical spot of the forewing.

melete. **P. melete** occurs in India in two pronounced local forms, of each of which two generations are known. A smaller, pure white subspecies, above scarcely striped with black, inhabits the North-West Himalayas and *ajaka. ajuta.* Kashmir; it is **ajaka** *Moore* (summer form) (vol. I, 20 g), the spring generation of which has been named **ajuta** by RÖBER. — In Sikkim, Bhotan and Assam occurs a more stately race, distinctly striped above, with yellowish ♀♀. *montana.* Under surface in both sexes dark grey instead of whitish; this is **montana** *Verity* (summer or rainy-season-form). — The South Chinese race is called *alpestris Verity*, being somewhat larger even than *montana*; — and *melaine.* that from Tibet has been named **melaina** *Röb.* (vol. I, 20 g); this presents in the ♀ a strongly darkened, distinct *mandarina.* subspecies, which, however, is in size inferior to the Himalayan race; *erutae Pouj.* occurs in Se-chuen, **mandarina** *Leech* in the mountains of China. — *melete Mén.* (vol. I, 21 b) is an Asiatic continental form of unknown locality (probably Manchuria or China), which was erroneously ascribed by its author partially to Japan, in *massiva.* which all the more recent authors have followed him. — In Japan occur three island races: **massiva** *subsp. nov.*, very large, ♂ with grey diffuse apical spot and indistinct submarginal patches; in the ♀ basal part and cell of the forewing as in *alpestris Verity* dusted with red-brown, hindwing with the vein-colouring unusually widened *juba.* distally. Main island of Japan. — **juba** *subsp. nov.* ♀ above pure white, cell only inappreciably dusted with *aglaope.* grey, approaches *montana Verity* above and beneath. Island of Tsu-sima. — **aglaope** *Motsch.* (= megamera *Btlr.*) is dark yellow beneath, above with broad stripes, very similar to *napi*, without the large interneural spots of *transiens.* the southern subspecies. Yesso. — **transiens** *Verity* is an almost entirely white form of the ♂ with less developed *dulcinea.* apical spot on the forewing; island of Askold. — **dulcinea** *Btlr.* is a form from Korea with white underside — *orientis.* and *veris Stgr.*, a spring form from Amur; — on the other hand **orientis** *Oberth.*, from Askold, was referred by its author to *napi*, but by VERITY more recently to *melete*. — It is an interesting fact, in any case, that in North Japan and Amur dark *napi* and *melete* forms are so intermingled that they can only be separated with difficulty. According to VERITY the scales of the two species are different.

devta. *P. krueperi Stgr.* (vol. I, 20 b) occurs in India in the well defined form **devta** *Nicév.* (vol. I, 20 b). This interesting species was discovered by DE NICÉVILLE in Ladak in 1879 on artificially-watered meadows; it is also not very rare in Kashmir, where it occurs at about 3000 m. Northwards it is distributed to Kashgar and Samarkand.

11. Genus: **Parapieris** *Nicév.*

Differs from *Pieris* only in the longer upper discocellular, which is due to the second subcostal vein of the forewing arising somewhat more proximally to the apex of the cell. High mountain butterflies, of rapid, irregular flight. — All the species are very shy; they prefer to remain on grassy places among blocks of rock, over which they fly away impetuously when anyone approaches them. On cloudy days they only appear when the wind drives away the clouds before the sun.

kalora. *P. callidice Esp.* (vol. I, 21 e) appears in the Indian region in the geographical race **kalora** *Moore*, which is more strongly black above, more densely and deeply spotted with green beneath. It is very local, flies only at the edges of glaciers or high snow-fields in company with Parnassiids, sometimes at elevations of 14,000 to 15,000 ft., whilst in Kashmir it seldom ascends above 3000 m.

chumbiensis. **P. chumbiensis** *Nicév.* (vol. I, 20 e), a rare species of Native Sikkim, which has some allies in West China, already dealt with in the Palaearctic part (vol. I, p. 50).

12. Genus: **Pontia** *F.*

For this long-known genus, resuscitated by SCUDDER and MOORE, RÖBER has introduced the name *Leucochloë* on p. 49 of vol. I of this work, in treating of the Palaearctic part of the butterflies. Very nearly approaches *Parapieris* with two subcostal veins branching off before the end of the cell. The fourth subcostal vein near the apex of the forewing is absent; it has apparently been pushed out beyond the margin of the wing in the course

of evolution. The egg is acorn-shaped. Larva and pupa described in the Palaearctic part (vol. I, p. 49). Only two species in India.

P. daplidice L., of which the local race **moorei** *Röb.* (73 a) inhabits Tibet, Kashmir and Baluchistan. *moorei.* A village butterfly, occurring commonly in those artificially watered oases of the Indian sterile mountain-valleys in which buckwheat, oats and millet are cultivated at elevations of about 3000 m. — **praeclara** *Fruhst.* is a much *praeclara.* larger race from South-West China. — **nubicola** *Fruhst.* is a small, dark mountain form from Kashgar, — and **aridia** *Fruhst.*, a strikingly black race, spotted with light green, from Shantung, North China, which is also known from Shanghai.

P. glauconome *Klug* (= vipasa *Moore*) (vol. I, pl. 20 f) I should regard as a local race of the preceding *glauconome.* if the larva and pupa were not described as different. Occurs in Afghanistan and the Punjaub on rocky, uncultivated slopes of the mountain valleys, where its food-plant grows.

13. Genus: **Synchloë** *Hbn.*

According to Scudder we must regard as type of this genus *belemia*, which is dealt with in detail in vol. I, p. 51 (as *Euchloë*). The genus is very nearly allied to Hübner's *Euchloë* (= Anthocharis *auct.*). In some species the fourth subcostal vein of the forewing is present; but it may also be absent and has probably, as in *Pontia*, been moved to beyond the margin of the wing.

S. lucilla *Btlr.* Upper surface lemon-yellow. Forewing with a black transverse spot at the apex of the *lucilla.* cell, apical area edged with black. Hindwing unspotted. Under surface pale yellow, costal margin ornamented with white dots. Hindwing black-scaled, with white costal spots and a white spot at the apex of the cell. ♀ somewhat larger with more extended black markings. Punjaub; is rarely brought to Europe.

S. belia L. (vol. I, 22 a) is represented in this region by **daphalis** *Moore*, a race with very fine greenish *daphalis.* yellow reticulate markings on a white ground and the apex of the forewing beneath suffused with brownish. Occurs from Chitral to Kashmir.

S. chloridice *Hbn.* (vol. I, 20 f), distributed through the whole of Asia, extends from Baluchistan *chloridice.* to Ladak, also occurring in the Indian region; inhabits altitudes of 15—17,000 ft.

14. Genus: **Huphina** *Moore.*

Costal of the forewing somewhat more curved than in *Appias*, hence the wing more rounded, cell broader and shorter than in true *Pieris* and *Delias*. The tufts of hair in the ♂♂ on the last abdominal tergite are wanting.

The colour of *Huphina* is always duller than in *Appias*; patches with mother-of-pearl or silky gloss never occur in them. Most of the species are white above with grey or black stripes and margins, only a few species are bright yellow or orange-colour on the under surface; on the other hand all nuances occur, from white to black, from yellow to red, not rarely green or yellow-green, and some species rival by their varied under surface the most brilliantly coloured *Delias*. All prefer the hot lowlands, although some species occur up to 5000 ft. at suitable places in the mountains. Like *Appias* they are fond of feeding at moist and dirty places and congregating in large crowds. They are unwearied fliers, but mostly move slowly, only the species of the *lea*-group darting through the air with great rapidity during the hot hours of the day. All show a tendency to local variation, are very susceptible to climatic influences, but less inclined to individual aberrations than *Appias*. Many species, however, are sexually dimorphic.

Larva on Capparideae, elongate, anal segment slightly bipartite, white-haired, mostly green. — Pupa with pointed head, thorax laterally and dorsally angled and raised, abdomen slightly ribbed, the last segments with small dorsal points.

H. nerissa is the longest known and most widely distributed species. The name-typical subspecies **nerissa** *F.* (= amasene *Cr.*) (64 b China; 64 c, d, e, 63 b Tonkin) is always larger than continental *nerissa.* Indian specimens. Cramer has figured the rainy-season-form as **coronis.** — For the North Indian local form it *coronis.* is best to employ the name **phryne** *F.* (64 a, b). **copia** *Wall.*, described from Bengal, is regarded as the name *phryne.* for its dry-season-form. — **dapha** *Moore* (64 a) is a local form from Tenasserim, Burma and Siam, distinguishable *copia.* by the greenish tint of the cell of the forewing and yellowish basal spot of the hindwing beneath, of which *dapha* itself constitutes an extreme dry-season-form with grey instead of yellow stripes beneath, while the rainy-season-form has as yet no name. — In South India and in Ceylon a very marked local race is developed: **evagete** *Cr.*, *dapha.* *evagete.* the rainy-season-form, and **zeuxippe** *Cr.* (64 a, b), its dry-season-form. The ♀♀ of this local race commonly *zeuxippe.* bear yellow-red submarginal spots on the forewing, such as are never found in North Indian *phryne.* — **cibyra** *cibyra.*

subsp. nov. is a race with the underside of the hindwing finely striped with grey also in the rainy-season-
lichenosa. form and with finely interrupted, very light apex to the forewing beneath; Formosa. — **lichenosa** *Moore* (63 a), from the Andamans, has the under surface to the hindwing almost entirely greenish, slightly marked with white. —
sumatrana. **sumatrana** *Hag.* (63 a), with predominantly yellowish under surface, only narrowly striped, and conspicuous by reason of its size. Sumatra. — The Javan race, **corva** *Wall.* (64 c), as is often the case, aproaches the continental Indian *phryne* much more nearly than its Sumatran sister race. — In East Java occurs a dry-season-form
corvina. with few markings, **corvina** *form. nov.* (64 c), which has the hindwing light yellow also beneath, without distinct stripes along the veins and with an isolated black spot between the anterior median veins. — The larva was already known to HORSFIELD in 1828, it is green with fine dorsal transverse lines. Pupa green with long lateral thoracic
dissimilis. points, striped with white. — **dissimilis** *Rothsch.* is a race very nearly allied to *corvina*, with pale yellow under
vaso. surface to both wings. Bali. — **vaso** *Doh.* (64 b), the opposite of the preceding, is strongly darkened above
physkon. also, cell of the hindwing beneath in the ♂♂ and the central areas broadly white. Sumbawa. — **physkon** *subsp. nov.* is much smaller than the preceding, with still darker stripes, the hindwing with the cell entirely green-brown or only narrowly striped with white. All the submarginal spots smaller, duller white. Very common on Lombok from the sea-shore up to the flower-covered plateau of Sambalun (4000 ft.). I met with the ♂♂ exclusively on wet sand, the ♀♀ only at flowers, on which they hang with folded wings, drinking greedily.

pactolicus. **H. pactolicus** *Btlr.* (64 c) replaces *nerissa* on Borneo, where the species occurs exclusively in alluvial land, but is very local and only found commonly in the south-east of the island, whilst I only obtained one ♂ from the north. ♀ still unknown. Forewing beneath as above, hindwing with the exception of the submarginal region beautifully light yellow, becoming darker towards the base. The white oblong submarginal spots separated from the yellowish area by a black band.

eperia. **H. eperia** *Bdv.* (64 d) has a white under surface to the hindwing, with the basal areas yellowish. A broad black submarginal band encloses moderately long, partly rounded, white spots. ♀ very rare, above and beneath
fora. somewhat darker. North and South Celebes, on wet sandbanks. — **fora** *Fruhst.* (64 d) is a smaller mountain form, in which the submarginal band of the hindwing is already marked above. Under surface slightly tinged with light yellow. Type taken at 4000 ft. at the peak of Bonthain, also from East Celebes in my collection.

eurygonia. **H. eurygonia** *Hpff.*, from the Toga Islands in Tomini Bay, in North-East Celebes, appears to be a transitional species from the *pitys* to the *phryne* group. Upper surface white, forewing with 7 triangular white spots in the reticulate black distal margin, hindwing with 3—4 similar patches. Under surface of both wings white, with sulphur-yellow base. Black distal margin of both wings with larger white spots than above; veins lightly marked with black.

celebensis. **H. celebensis** *Rothsch.* (64 d). Forewing at the end of the cell without the black tooth which extends to the distal margin. Under surface as in *eperia*, but with long, radiate white submarginal streaks. The black border of the hindwing distally broken up into black dusting. ♀ as in *eperia*, but with the submarginal stripes of the hindwing longer. South Celebes; also taken by me in December at Toli-Toli in the north of the island and always found in company with *eperia*.

H. nadina occurs nearly always in company with *nerissa*, but is less widely distributed and is wanting on Java and the small Sunda Islands. The rainy-season-form as in *nerissa* larger, above more broadly black, that of the dry season beneath grey instead of greenish yellow. Larva and pupa on Capparis, scarcely distinguish-
nadina. able from those of *nerissa*. — **nadina** *Luc.* (63 b) is founded on the rainy-season-form; **nama** *Moore* designates
nama. somewhat lighter specimens of the intermediate form, less broadly margined with black in the female; and **amba**
amba. *Moore* (64 a) is the name for the extreme dry-seasonal form, whose ♀♀ are above almost as light as the ♂♂ and beneath grey or yellowish sand-colour. Between the extremes there are transitions of various grades. Sikkim to
remba. Tonkin and Hainan, Burma, Siam, Annam. — **remba** *Moore* differs in the black distal margin of the forewing extending to the cell and in having the upper surface of the hindwing distally dusted with blue-grey. Apex of the forewing and the upper surface of the hindwing greenish yellow with smoke-brown spots. ♀ beneath as the ♂ and above with a more obliquely placed, somewhat narrower, white central area on the forewing than *cingala*. The
liquida. dry-season-form **liquida** *Swinh.* is beneath lighter grey-green and both wings correspondingly more narrowly
cingala. margined with black. *remba* is a forest butterfly, and occurs all the year round. — **cingala** *Moore* (63 b) has a regular dark apical border on the forewing and beneath darker green ground-colour, which, however, is covered with light brown spots; ♀ with whitish instead of greenish yellow basal spot on the upperside of the hindwing.
andamana. At 2—4000 ft., a quick flier and difficult to catch, rather rare; Ceylon. — **andamana** *Swinh.* approaches the rainy-season-form of *nadina*, but has a less broad black distal margin to the forewing. The ♀ above predominantly white, but more distinctly spotted with black than *amba*-♀♀, the under surface of the hindwing somewhat darker
fawcetti. green with more conspicuous postdiscal bands. Andamans. — **fawcetti** *Btlr.* is a more specialised island race with sharply defined, deep black distal margin on the upper surface of the hindwing also. Under surface deep moss-green with dense black dusting. The very rare ♀ on the upperside of the hindwing partly scaled with blue. partly with yellow-green, the black margin on the forewing extending to the cell. Sumatra, from 2—5000 ft, —

andersoni *Dist.* (65 c) is beneath so different that it can only be recognised as belonging to *nadina* by the yellow-green dusting at the apex of the forewing; the hindwing is light orange-colour with a beautiful yellow longitudinal spot which extends beyond the cell. Malay Peninsula, apparently very rare. — **eunama** *Fruhst.* (65 c), above of a milky instead of yellowish white ground-colour, beneath with light moss-green tinge, without yellowish admixture. Formosa, ascending to 4000 ft., common.

H. perimale must be accepted as the oldest name for a widely distributed, extremely variable species, the forms of which are figured in the three lower rows of plate 65. There are nearly 30 island races known, a remarkable instance of the wide severance which is effected by a few knots of salt water of the ocean which isolates butterflies whilst uniting peoples. The butterflies, so far as is known, always live near the coast, where they are fond of visiting flowers not very high above the ground and when startled hide in the eucalyptus and thorn bushes with which the small Sunda Islands are so luxuriantly overgrown. Godart in 1819 described a *perimale*-race as *Pieris pitys* from Java. Two decades later (1836) Boisduval transferred the locality of this to Timor and mentions a „*P. rachel*" from Java. Although I have not myself found it there, its occurrence on Java is not improbable, so much the more as I have received it in large numbers from Bawean. As Godart's description agrees very well with a form from Timor, we begin here with **rachel** *Bdv.*, from Java. — **aeliana** *Fruhst.* (65 d), from Bawean, doubtless nearly approximates to it. The ♂ beneath has the cell and two median areas light yellow, but both sides of the submedian pure white; base dusted over with greenish; the subapical spots, white on the upper surface, a beautiful yellow, varying in number from 2 to 5. Hindwing a beautiful light yellow. Distal margin moderately broad, more extended than above, with the yellow dot also mentioned by Boisduval in *rachel* between the radial veins. ♀: under surface of the forewing white also in the cell, hindwing light ochre-yellow. Flies in July-September. — **aelia** *Fruhst.* is a larger race, still more broadly margined with black above, with two yellowish white subapical patches. Under surface as in *aeliana*, but more broadly margined with black-brown. Island of Kangean. — **mentes** *Wall.* has in the ♀ above the white basal area of the forewing already somewhat darkened by dense black scaling; the ♂ differs from *aeliana* in the broader distal margin and the presence of only two subapical patches. Under surface: forewing of the ♂ greenish yellow, hindwing dark lemon-yellow, ♀ light ochre-yellow. Lombok, only taken near the coast. — **synchroma** *Röb.* has somewhat narrower black distal margin, moreover the underside of the forewing is again white posteriorly; Flores, Alor, Lomblen. — In **lucia** *Fruhst.* (65 e) the upper surface of the ♀ is often powdered over with grey-brown almost throughout and the whole of the cell of the forewing becomes black-brown. Beneath the distal margin extends proximally beyond the edge of the cell. Sumbawa. — **pitys** *Godt.*, from Timor, differs according to the figure from all the preceding in the uniform yellow tinge of the under surface and in the equally broad black distal margin of both wings above and beneath. — **wetterensis** *Gr.-Sm.* is the rainy-season-form, and **ellina** *form. nov.* (65 e) the dry-season-form, from the island of Wetter. The under surface of the forewing in both is white; that of the hindwing a beautiful yellow in the wet season form, earth-coloured in that of the dry period. Often the apex of the forewing beneath is also suffused with grey and in both the ♂♂ and ♀♀ of the intermediate form the distal band of the hindwing begins to be broken up or to assume a grey-brown colour. — **pygmaea** *Röb.* is a dwarf form from the island of Letti, from which **babberica** *Fruhst.* differs by a somewhat broader black marginal band; island of Babber. — **pityna** *Fruhst.* is another dwarf form with the most broadly diffuse black border to both wings; island of Dammer. — **kuehni** *Röb.* inhabits the remote island of Kabia, south of Celebes; it has the narrowest black distal margin and the lightest yellow under surface to the hindwing of all the known races. The border of the forewing is more deeply emarginate and before the apex are placed three yellow patches, whilst in *pityna* these are usually entirely absent. — **consanguinea** *Btlr.* is above marked exactly like *bolana*, except that the apical spot is reduced; Tenimber. — **bolana** *Fruhst.* (65 f) forms by its size a transition from the dwarf forms of Micromalayana to the more imposing races of the Papuan region. The subapical spots of the forewing beneath very large, beautiful yellow, as well as the upper surface of the hindwing of the ♂, that of the ♀ light ochre-yellow. Key Islands. — **perictione** *Fldr.* is nearly allied, with the black distal band on both wings more deeply excised proximally. Underside of the hindwing in the ♂♂ light ochre-yellow, tinged with orange in places. Aru. — **wallaceana** *Fldr.* is unknown to me in nature. The underside of the hindwing is said to be saffron-yellow, the distal margin with violet sheen; Waigeu. — **dohertyana** *Gr.-Sm.*, similar to the figured *mithra* except that the black marginal band is straighter, and the ♀ is still more intensively tinted with greenish; Dutch and German New Guinea. — **latilimbata** *Btlr.* (= hartei *Ribbe*) has a narrower and still more sharply defined black distal margin to both wings. Under surface of the hindwing in the ♂♂ light-yellow. British New Guinea. — **mithra** *Fruhst.* (65 e) has in the ♂ white, in the ♀ yellow subapical dots on the forewing. Underside of the hindwing in the ♂♂ dark yellow, that of the ♀♀ orange-yellow; the black distal margin broader than in New Guinea specimens; Fergusson Island. — **chrysopis** *subsp. nov.* approximates to *mithra*, but is of smaller size, ♀ above entirely white, distal border straighter, ♀ almost without subapical dots. Under surface also in the ♀ lemon-yellow, hindwing with a yellow dot between the radial veins; Mefor. — **leucophorus** *Gr.-Sm.* (65 d) has beneath on the forewing three yellow and three white submarginal spots and 2—3 on the very narrow distal border of the hindwing. Kiriwina. — **smithi** *Btlr.* (= pallida and pallescens *Gr.-Sm.*) very closely approaches it; it bears four white oblong patches in the distal band of the hindwing. Biak Island in Geelvink Bay. — Oberthür mentions a race from the neighbourhood of Yule Island, in which the ♀ is sulphur-yellow beneath. This form

rachel. aeliana. *aelia.* *mentes.* *synchroma.* *lucia.* *pitys.* *wetterensis. ellina.* *pygmaea.* *babberica.* *pityna.* *kuehni.* *consanguinea.* *bolana.* *perictione.* *wallaceana.* *dohertyana.* *latilimbata.* *mithra.* *chrysopis.* *leucophorus.* *smithi.*

scyllara. belongs perhaps to *latilimbata Btlr.* — **scyllara** *McLeay* (65 d) is a subspecies so rich in forms that it has received a whole series of names. The figure shows the extreme rainy-season-form (*scyllara*), with white under surface to the hindwing. A second form, without a name, has this pale lemon-yellow. *nabis.* **nabis** *Luc.* denotes one with narcissus-yellow, and *lanassa.* **lanassa** *Btlr.* one with saffron-yellow ground-colour. *periclea.* **periclea** *Fldr.* is an intermediate form with light brown apical tinge on the forewing and basal area of the same colour on the hindwing, under surface with very broad black submarginal bands. Finally, *narses.* **narses** *Wall.* (65 d) is the extreme dry-season-form, with grey, sand-coloured under surface, on which the black submarginal bands are narrowed. Australia, especially *perimale.* from Norfolk Is. in the north. — **perimale** *Don.* is a relatively small subspecies with very narrow distal border to both wings, which on the forewing bears a row of 6 white subapical patches. The first described is the extreme dry-season-form, similar to *narses*, but beneath darker earth-brown with very broad black transverse bands, traversing the entire forewing. ♀ broadly margined with black, with 5 white submarginal spots on each wing. *amarella.* Wallace has described a transitional form as **amarella** and that of the wet season has a light yellow ground-colour on *acrisa.* the hindwing beneath. New Caledonia. — **acrisa** *Bdv.*, erected on the rainy-season-form, has a white under surface to the hindwing. A second form has the hindwing and the apex of the forewing sulphur-yellow. An intermediate form has a light brown hindwing, and the extreme dry-season-form, with earth-brown under surface *terranea.* recalling *perimale*, has been named **terranea** *Btlr.* The ♀ of the rainy-season-form is yellow also above, with very broad distal margin to the hindwing, especially towards the costa, which only contains traces of whitish *perithea.* dusting. Island of Lifu, east of New Caledonia. — **perithea** *Fldr.* (= inopinata *Btlr.*) has been described from the ♀ of the rainy-season-form, with light yellow ground-colour on the hindwing, which is basally suffused with *agnata.* darker yellow. Unknown to me in nature; Fiji Islands. — **agnata** *Gr.-Sm.* again approaches the Papuan type in the character of the markings, in many respects resembling *mithra*, from which it differs principally in having the black distal margin on the underside of the hindwing only half as broad anally; Rubiana and Guadal- *maedonaldi.* canar, Solomon Islands. — **macdonaldi** *Ribbe*, described as *Tachyris*, has beneath a more extended distal margin, *discolor.* which is ornamented with small, indistinct yellowish spots. Bougainville (Solomons). — **discolor** *Godm. & Salv.* (63 c) is above in the ♀ light yellow; in the black distal border, which extends to the cell, are placed in both sexes 3—6 white oblong spots. Unknown to me in nature; figured from the types in the British Museum. Ugi and Ulana (Solomons).*)

quadricolor. **H. quadricolor** *Godm. & Salv.* (65 f) possibly represents *perimale* in the Bismarck Archipelago. ♀ above essentially darker than the ♂. The butterflies were found flying over the damp sea-shore, occasionally settling on a yellow composite; the ♀♀ rare, about as 4: 100 to the ♂♂. New Pomerania, New Mecklenburg, New Lauenburg and Nusa-Laut. There occur, but very rarely, also specimens without the row of yellow submarginal spots on the underside.

maculata. **H. maculata** *Sm.* is a peculiar, isolated species, which from its pointed forewing might be a *Tachyris*, were it not that the hair-pencil of the abdomen is wanting. Upper surface pure white, with narrow black sub, apical band on the forewing and 4—5 small black intermedial streaks on the hindwing. Evidently very rare since it was not found by Ribbe and Dahl. ♀ still unknown. New Pomerania.

affinis. **H. affinis** *Vollenh.* (58 b) appears to replace on Celebes the *pitys* of the small Sunda Islands. The butterflies fly slowly and heavily at the edges of the woods. There are two seasonal forms, a small dry-season-form which is dull grey above and a larger rainy-season-form with pure white bands. The ♀ is very rare, larger, with rounder wings, and with a grey-scaled median area on both wings. Beneath the forewing is white except for the sharply defined black distal border, the hindwing dull yellow. North and South Celebes. De Nicéville has based on *affinis* the untenable genus „*Aoa*" (sic).

boisduvaliana. cirta. semperi. balbagona. **H. boisduvaliana** *Fldr.* (65 f) represents *pitys* on the Philippines. The typical form has been described from Luzon. — As **cirta** *subsp. nov.* I designate the island race from Bohol, which has a much narrower black distal border. — **semperi** *Stgr.* (65 f) on the other hand is a form from Mindanao with very broad border; — **balbagona** *Semp.* is a much darkened island race with smaller whitish discal spots on both wings. Camiguin de Mindanao. The under surface of all the races is white on the forewing, on the hindwing light yellow to orange-yellow, the black distal bands on both wings slightly scaled with violet or yellowish. The species is nowhere rare and flies all the year round with the exception perhaps of January to March.

With **H. lea** begins a well defined group of beautifully coloured species, which without exception are characterised by a white forewing and in contrast to it, a yellow or orange-coloured hindwing. All the species inhabit the edges of forests or open woods and fly restlessly, in the rainy season fluttering slowly from flower to flower and being then extremely easy to catch, but in the dry season or on very hot days shooting along wildly, so that it is only with great difficulty that even one of them can be captured. In spite of the commonness *lea.* of the species nothing is known with regard to the early stages. — **lea** *Dbl.* (64 e). Under surface of the forewing white with black-margined cell, moderately broad black apical dusting, which includes three white

*) It is not impossible that one or other of the 36 *perimale*-forms here recorded may be really a separate species; but this can only be proved by breeding from the larva or by an examination of the organs of copulation, for which at present there has been no opportunity.

discocellular stripes and is ornamented with 2—3 yellow patches. Hindwing entirely light yellow, anal margin orange-coloured, the distal band, which in the ♀ is somewhat broader, moderately wide, brown-black adorned with some yellow spots. — **malaya** *Fruhst.* is above somewhat more broadly margined with black, hindwing with *malaya.* the anal half entirely dark orange-yellow. Forewing of the ♀ predominantly black with oblong white areas, hindwing in the cell a beautiful light yellow, anally brown-red. Under surface much more extended orange-colour than in the allied races. Malay Peninsula. — **siamensis** *Btlr.* is a much lighter race, upperside of the hindwing *siamensis.* in the ♂ extended yellow and only posteriorly light orange-colour. The greater part of the forewing of the ♀ white, hindwing lighter yellow and more yellow-brown than *lea* and *malaya*. Siam, common from December to April, often associates with the crowds of *Huphina dapha* and *Appias libythea* at wet places on the ground. — **amalia** *Voll.* inhabits Sumatra. Veins of the forewing more broadly black than in *lea*, the brown-red colouring *amalia.* of the hindwing in the ♀♀ more restricted. The black reticulation on the under surface more extended than in *lea*. — In **montana** *Fruhst.* (65 a) the reddish tinge of the hindwing has almost entirely disappeared and the *montana.* black transverse striping is essentially reduced. Kina Balu. — **meridionalis** *Fruhst.* is the race from South-East *meridionalis.* Borneo, in which the black distal border of the hindwing extends to the cell, the cell itself being suffused with light yellow. Under surface of the hindwing with large white spots beyond the cell, which are absent in *montana*. — **hespera** *Btlr.*, from Sarawak and Labuan (Borneo); the ♀♀ with very broad brown tinge on the upperside of the *hespera.* hindwing and broad, confluent transverse stripes on the underside. — **natuna** *Fruhst.* (64 e) has very narrow *natuna.* black distal borders to both wings, the ♀ above with a finer black reticulate pattern than Borneo specimens. Yellow subapical spots on the forewing, a yellow anterior part to the hindwing, which in the posterior half is suffused with light chestnut-brown. Hindwing beneath almost without black distal margin, but there is a moderately broad submarginal band instead, distally bordered by large yellow subterminal patches. Natuna Islands.

H. judith *F.* (65 a, b) replaces the preceding species on Java; it is common everywhere up to 2000 ft. *judith.* where there are open or dense woods, at the borders of which, as also in the coffee plantations, it is to be met with all the year round, sometimes in innumerable swarms. The species is continuously on the wing from 9 o'clock in the morning till about 5 in the evening and especially visits flowers. East and West Java, Bali.

H. selma *Weym.* (65 b) is perhaps only a local race of the preceding; the ♀ is very rare. Nias. *selma.*

In the midst of the area of distribution of *judith* and *selma* occurs on the island of Engano a distinct species, **H. ethel** *Doh.* (65 b), whose ♀ has curiously a much closer resemblance to *zisca* from the Philippines than *ethel.* to *judith* and *selma*, and beneath is noteworthy for the large yellow subapical spots on the forewing and a broad black submarginal band on the dark yellow ground of the hindwing.

H. naomi *Wall.* is the predominant butterfly of the island of Lombok, where it occurs at elevations of *naomi.* from 2—4000 ft. The plateau of Sambalun especially, which at the end of April presents one expanse of flowers, is enlivened by this species. The ♂♂ rest at the sandy edges of the brooks, only rarely moving, whilst the ♀♀ flutter from flower to flower. Two seasonal forms of the ♀♀ may be differentiated: that of the rainy season similar to the *aga*-♀ figured, but still more broadly striped with black and beneath with reddish orange-coloured discal spots, and **pseudamba** *form. nov.* with predominantly grey-white upper surface narrowly margined with black *pseudamba.* and yellow and grey-yellow, even whitish under surface. — **aga** *Fruhst.* (64 e, f) is a local race from Sumbawa, *aga.* darker in the ♂, in the ♀ with more extended reddish yellow tinge on the hindwing above. — **oberthueri** *Röb.* *oberthueri.* is very nearly allied to it, but with larger yellowish patches on the black distal margin of the hindwing beneath in the ♂♂ and light lemon instead of reddish yellow hindwing in the ♀♀, only narrowly bordered with black. Flores. — **eirene** *Doh.* has likewise lemon-yellow under surface to the hindwing and in the arrangement of the *eirene.* black markings approximates much more to *judith* from Java than to *naomi*; Sumba.

H. aspasia is the name-type of a collective species distributed from the Philippines over the Moluccas to Waigeu. It is very susceptible to climatic influences and is consequently divided into a large number of local races. — **olga** *Eschsch.*, from Manila on Luzon, is the most northerly branch. ♂ above similar to *zisca*, but *olga.* smaller and with less prominent black transverse stripes on the forewing. — In North-West Luzon it has developed a pronounced winter and local form, **anaitis** *subsp. nov.*, with slight blackish dusting; the ♀♀ light yellow *anaitis.* on the hindwing above, with the forewing almost entirely white. The ♂♂ of the summer rainy-season-form, **tergelia** *form. nov.*, from Central Luzon, have somewhat more extended black dusting; the hindwing assumes a darker tone, the ♀ has on the upperside of the forewing broad black stripes and large yellow patches; the hindwing is darker yellow, densely scaled with black and margined with black almost to the cell. — According to SEMPER *anaitis* owes its existence to the very considerable variations of temperature in North-West Luzon, where the dry period is at the same time the coldest, whilst at Manila, where *olga* occurs, the temperature is subject to less change. Between these stands *tergelia* with rich colours, which on Mindoro and Negros increase still more; there, especially in the ♀, the yellow of the hindwing is deeper, the black dusting more extended: this is **rhemia** *rhemia.* *subsp. nov.*, type from Mindoro. Seasonal forms also are developed on these islands, especially on Bohol, where

the seasons are less sharply separated and the temperature varies still less, indeed scarcely at all (SEMPER). — On Camiguin de Mindanao occurs another noteworthy island form, which differs from *zisca* in the more sharply
poetelia. defined distal border of the hindwing in the ♀ and the darker yellow ground-colour: = **poetelia** *subsp. nov.* — On Mindanao itself, particularly in the east, where the full force of the monsoons is experienced, enormous volumes of water being discharged over the woods of the island, the dark colouring attains its greatest intensity:
orantia. **orantia** *subsp. nov.* The yellow of the hindwing has an orange tinge, the white areas of the forewing are still further
zisca. suppressed by black. — This tendency to darkening exists also in **zisca** *Fruhst.* (65 a), from Bazilan, but in this the areas of the forewing are white instead of yellowish, as in *orantia*, and the hindwing lemon-yellow instead
irma. of orange-coloured. — **irma** *subsp. nov.* (64 f) has also on the hindwing white interneural areas; Jolo Archipelago. —
olgina. **olgina** *Stgr.*, from Palawan, has still more extended and more milky white stripes on the forewing and the hindwing
phokaia. is only in the cell slightly tinged with yellowish. — **phokaia** *subsp. nov.*, from the island of Balabac, is in both sexes even lighter than *olgina*, the black veins and the distal margin appreciably narrowed, the hindwing beneath
emma. strikingly pale. — **emma** *Voll.* (64 f) shows especially broad black stripes on the forewing, which, however, still leave room for relatively large white subapical spots. ♀ beneath predominantly black, with yellow submarginal spots and green-dusted, otherwise light ochre-yellow under surface to the hindwing; Batjan, Halmaheira, Moro-
aspasina. tai. — **aspasina** *Fruhst.* (65 a), smaller and much darkened; in the ♂ the white subapical patches of the forewing are suppressed, the hindwing above and beneath more reddish yellow than in *emma*. ♀ above predominantly yellow, without whitish areas; under surface of the hindwing light yellow with red-yellow submarginal patches.
hester. Veins in both sexes without black colour; Obi. — **hester** *Voll.* (63 a) approaches it most nearly, but the under
aspasia. surface of the hindwing in both sexes is light lemon-yellow. Waigeu. — **aspasia** *Stoll* (64 f) is the nymotype of the whole group; the ♂, very similar to *hester*, has rather broadly black-edged veins on the forewing and dark orange-tinted hindwing; ♀ on the under surface of the hindwing without the black reticulate markings of *emma*; forewing also beneath with very fine black reticulation, hindwing with only the vestiges of a submarginal band,
jael. otherwise light yellow with darker margins; South Moluccas. — **jael** *Wall.* approximates to *aspasia*, but the ♀ is still more narrowly margined with black and both sides of the hindwing are light lemon-yellow with a slight admixture of reddish; Buru.

bathseba. **H. bathseba** *Snell.* is a *mixtum compositum*. The ♂, above scarcely distinguishable from *aspasia*, only like *jael* with yellow instead of black costal margin to the hindwing, unites on the under surface the pattern of the forewing of *judith* with that of the hindwing of *naomi* and *leal* The ♀ is beneath intermediate between *naomi* and *ethel*, and above resembles on the hindwing *orantia* from the Philippines and on the forewing *aga* from Sumbawa. Also zoogeographically considered *bathseba* is an enigma, with its *aspasia*-colouring of the ♂♂ between Java, which produces the light yellow *judith*, and Lombok, where occurs *naomi* with the hindwing half white and half yellow! Hence in *bathseba* we have a „missing link" between *lea* from the western part of the Archipelago and *aspasia* from the Moluccas. Island of Kangean, to the north-east of Java. It is most interesting how a local race of *aspasia* could be developed on Kangean, whilst only a few miles to the south, on Bali, the Javan *judith* and to the south-east *naomi Wall.* occur. The unexpected occurrence of an *aspasia*-race so far west of its proper region, the Moluccas, might give rise to the supposition of importation by the wind or some other migration. But here, as with so many other island races, it is quite out of place to suppose migration or importation as an explanation of their occurrence. The butterflies are something certain, which probably already existed when the whole of South Asia presented a compact mass of land. Hence when by tectonic causes some islands are divided off, the butterflies and other insects, mollusca, etc., remain at the same place. But on these fragments of an earlier continent, or island as large as a continent, varied climatic and atmospheric influences are now at work, which act on the *a priori* present species, incline them to variation and in the course of innumerable ages mould them into that which we to-day recognise in the Archipelago as a geographical form or an island race, and in some cases even regard as a good species.

aspasia is wanting in the Celeban subregion, where it is apparently represented by **H. timnatha,** a species of which five subspecies are known, and of which quite a series may still be looked for, as each of the five
timnatha. islands around Celebes produces a separate race. **timnatha** *Hew.* (64 d) is described from North Celebes. The under surface as the upper, except that the black vein-stripes are deep black and rather sharply defined. The hindwing is very similar to that of *celebensis*, with broad black distal margin, which encloses six whitish spots. The base is tinged with dark yellow. The strongly dimorphic ♀ resembles that of *sorror*, but has the spots on the upper surface of both wings narrower and yellowish. Minahassa, ♂♂ common, ♀♀ very rare. In Gorontalo
filia. on the east side according to VOLLENHOFEN a smaller and darker local form occurs. — **filia** *Fruhst.* is a larger and much lighter race with the black bands and blue-grey dusting on the hindwing reduced. Base of the hindwing tinged with light yellow, extended white areas beyond the cell, the submarginal spots of both wings larger, those
sorror. of the hindwing light yellow instead of whitish. South Celebes, waterfall of Maros. — **sorror** *Fruhst.* (64 e) is a smaller island race. Forewing more blackened, the blue-grey distal margin of the hindwing lighter and intersected by thinner vein-stripes. Under surface with broadened black bands, hindwing with reduced dark yellow basal area, white cell, distal margin extended to the cell, ornamented with smaller white-yellow patches. Sula

Mangoli. — **filiola** *Fruhst.* is still smaller, beneath only darker, with strongly restricted white areas. Hindwing with green-yellow basal tinge and submarginal spots of the same colour. Sula Besi. — **aurulenta** *Fruhst.* closely approximates to *sorror* above, but differs from it and other island forms by the intensively orange-coloured tinge of the hindwing beneath and from *timnatha* by the reduced submarginal spots of both wings. Bangkai. *filiola.* *aurulenta.*

With **H. temena** begins a series of species which exclusively inhabit Micromalayana; they are above without exception white in the ♂ and have a moderately broad black distal margin, but beneath rival the most magnificent *Delias* by their brilliant combination of black, red and yellow, either laid on in sharp contrast or delicately merged into one another. Four subspecies are known, which all inhabit the hot coast-districts, thickly overgrown with thorns, of their isolated native islands and in my experience never ascend even to 300 m. — **H. tamar** *Wall.* (55 e) has above the broadest black distal margin to the forewing, is beneath a beautiful yellow and spotted with black; very rare, described from Bali, but has also been observed in single migratory specimens in eastern Java. — **temena** *Hew.* (63 d), from Lombok, has a much lighter basal area above, more broadly striped with white on the forewing and more extended yellow on the hindwing, than **lenitas** *subsp. nov.* (63 d), from Sumbawa, in whose ♂♂ beneath the forewing is traversed by broader black transverse stripes and the hindwing tinged with much darker red-orange-colour and traversed by a stronger black submarginal band, produced basad into a longer point. The ♀ is almost entirely black on the forewing, the veins of the hindwing more broadly black, but the cell of the forewing in the ♂ much lighter than in *temena*. — **hyele** *subsp. nov.*, from the island of Lomblen, represents the albinistic extreme of the *temena*-series; hindwing of the ♀ above light yellow, ♂ on the underside without a trace of black colour on the veins, in the light orange-yellow basal area of the hindwing with very reduced black proximal bordering to the red submarginal spots, which as in the ♀ are more extended. — On Lombok I found *temena* exclusively at somewhat overshadowed, marshy pools, befouled by grazing cattle or horses, where the ♂♂ rest with the wings folded, displaying to the onlooker the gorgeous under surface, and drink greedily. They are, however, very shy, difficult to catch and very lively in the net. The ♀♀ are met with in company with those of *Ixias reinwardti* in the thickest thorny Euphorbia-bushes, in which, when frightened, they disappear near to the ground. *tamar.* *temena.* *lenitas.* *hyele.*

H. julia *Oberth.* (65 c) is beneath a faithful copy of *Delias faseiata Rothseh.* from Sumba; ♂ beneath similar to that of *temena*, but with narrower black transverse bands and lighter yellow subapical spots. Hindwing as in *temena*, but with light yellow basal area, which contrasts vividly with the broad fiery red costal margin and the red submarginal patches with their thin black bordering. ♀ beneath as the ♂, but with whitish streaks along the veins. Sumba, discovered by Doherty. — **calliparga** *subsp. nov.* is larger, ♀ above on the forewing predominantly black with narrow white subapical patches. ♂ beneath with feebly indicated black submarginal band, the whole of the apical area tinged with light yellow; ♀ beneath likewise with more extended yellow apical tinge and darker hindwing, less shaded with white. Sumbawa. *julia.* *calliparga.*

H. laeta *Hew.* (65 c), described from Timor, but apparently also not very rare on the island of Wetter. ♀ beneath as the ♂, but with lighter yellow apical spots on the forewing and light yellow under surface to the hindwing, on which the scarlet marginal spots are proximally bordered by a complete narrow black submarginal band. *laeta.*

H. abnormis *Wall.* (63 b) has in common with **euryxanthe** *Honr.* (63 c) an isolated light red spot in the cell of the forewing. Both inhabit Dutch and German New Guinea. — **ornythion** *Godm. & Salv.* is an allied form from British New Guinea with broader, more obliquely placed, almost triangular apical spot on the forewing, which in the ♀ extends to the cell. Hindwing of the ♀ dusted over with blue-grey above. *abnormis.* *euryxanthe.* *ornythion.*

H. ladas *Gr.-Sm.* (63 b) has beneath yellow instead of red spots; the red longitudinal spot of the forewing is absent, on the other hand the base of the hindwing has a distally pointed yellow triangular patch. *ladas* inhabits elevated localities, and it is the only Pierid which occurs in the midst of the gloomy primeval forest on Mt. Gelu in German New Guinea at about 1500 m even during the height of the rainy season and settles on the sandy banks of the water-courses. *ladas.*

H. persephone *Stgr.* (= odyssia *Fruhst. i. l.*) (63 d) was formerly only known in one defective male specimen and described as *Delias*. I have ♂♂ and ♀♀ from Waigeu. ♂ above like *ornythion*, ♀ the same but with still broader black distal margin to both wings. Beneath both sexes are alike except that in the ♀ the yellowish apical spot on the forewing of the ♂ is absent. *persephone.*

H. dohertyi *Oberth.* is an allied but distinct species. ♂ above only with a very narrow black apical margin, otherwise pure white. Under surface of the forewing likewise white with black apex and a more extended yellow subapical spot. Hindwing as in *persephone*, only somewhat lighter and sprinkled with some grey scales before the distal margin. Ansus on the island of Jobi. *dohertyi*

15. Genus: **Appias** *Hbn.*

The genus *Appias*, better known under the newer name of *Tachyris*, approximates to the true *Pieris*, but may be distinguished from these by the narrower, longer cell of the hindwing and the presence of a thick hair-pencil on the abdomen of the ♂♂ and by the apex of the forewing being sharply pointed in most species, sometimes even considerably produced. The wing-contour and the style of colouring vary more than in *Pieris s. str.*; likewise the sexes show a tendency to excessive dimorphism. Moreover most of the species are liable to climatic variations to a considerable extent. — Larvae long, mostly green, slightly impressed, posteriorly somewhat narrowed and with two points at the anus. Pupa fastened closely to leaves; the wing-cases without keel. Head with short snout, dorsum slightly raised, laterally with 2 spines; duration of the pupal stage about a week. All the *Appias* are strong, restless fliers, which hurry about everywhere, even near human habitations, gardens, fields and edges of woods, seldom rest on flowers, but are fond of congregating in large numbers on moist places; migratory swarms of *Appias* have been several times observed in Ceylon. — The larvae of *A. libythea* and *taprobana* eat one another when short of food; they also attack pupae of their own species, larvae which are moulting, and larvae and pupae of other Pierids.

A. libythea. A widely distributed species with striking sexual dimorphism. It presents one of the clearest examples of the variation of the Pierids through climatic influences. I have been able unmistakably to observe the gradual modification of the darker markings of the rainy season into the lighter colouring of the dry season.

libythea. Two local races may be distinguished in the Indian region: **libythea** *F.* (= rouxi *Bdv.*) (58 a), indigenous to the Punjaub, Bengal, West and South India and Ceylon, which is somewhat smaller. The rainy-season-form

zelima. ares. of the ♀ is **zelima** *Cr.* (= retexta *Swinh.*), the dry-season-form of the ♀ being **ares** *Swinh.* (58 a). But in

zelmira. Tenasserim, Annam, Indo-China, also in Assam and Sikkim and even sometimes in the plains of Bengal, **zel-**

olferna. irvini. **mira** *Cr.* (58 a) (rainy-season-form) is met with. An intermediate form is **olferna** *Swinh.*, while **irvini** *Swinh.*

sopara. is a white-yellow, extreme dry-season-form without markings (58 a 1). **sopara** *form. nov.* is a rainy-season-form similar to fig. 7, pl. 58 a, but with yellowish instead of whitish areas on the upper surface of both wings; Siam,

peducaca. Assam. — **peducaea** *subsp. nov.* ♂: apical area of the forewing strongly darkened, so that the white strigae are sometimes reduced to thread-like lines. ♀ of the rainy-season-form above and beneath with narrower black markings than in the continental specimens; Luzon, Mindoro, common. — Larva on Crataeva and Capparis; pupa often producing the butterfly in only four days. The eggs are laid singly. The butterflies ascend to 3000 ft.

hombroni. **A. hombroni** *Luc.* (59 e) appears to represent *libythea* on Celebes. The contour of the wings is somewhat similar to that of the genus *Prioneris*. — In East Celebes specimens occur in which the apical colour is broken

lombugensis. sulanorum up into grey spots; this is **tombugens's** *Fruhst.* Tombugu, Kendari; flies in December, January. — **sulanorum** *Fruhst.* (59 e) on the other hand is much darkened in both sexes, so that in the ♀ the white distal spot of the forewing is almost suppressed.

lyncida. **A. lyncida** *Cr.* is the oldest name of a widely distributed collective species, which in addition to the climatic varieties occurs in a large number of island races, some of which are based upon slight, some upon more

hippoides. material variations. — **hippoides** *Moore* (pl. 58 d called *hippo*) appears in three seasonal forms: that of the rainy season with the ♀ as in *formosana* (58 e), but narrower white transverse bands, that of the transitional period, to which the ♀ figured belongs, as it occurs in Siam and Annam in January and February — and that of the

vacans. dry season, **vacans** *Btlr.* (= epicoena *Swinh.*) (58 d, as *epicoena*). In the latter the under surface commonly varies also, assuming an orange instead of light yellow colouring. There occur very rarely also ♀♀ with yellow

lurida. instead of white areas on the forewing above; these are **lurida** *form. nov.* According to Doherty the ♀♀ are found exclusively in the deep shade of the forest, where they sit about on leaves as if lost and from time to time fly

latifasciata. up and down on sunny paths. *hippoides* is distributed from Bengal to Tonkin, Annam and Siam. — **latifasciata** *Moore* is distinguished from *hippoides* by the dense and extended black dusting at the anterior cell-wall and the subcostal of the hindwing beneath and by the broader, strongly dentate black distal margin of both wings. The eggs are laid in clusters. Larva on Crataeva religiosa. Ascending from the plains to 4000 ft. Occurring

taprobana. in South India from Kanara onwards. — **taprobana** *Moore* is a smaller race from Ceylon, with somewhat broader and more deeply dentate distal margin to both wings and dark ochre-yellow tinge on the hindwing beneath. The

aperta. paler dry-season-form is **aperta** *Btlr.* Larva dark green with small black dots, a whitish sublateral line and light green ventral side, lives on Crataeva religiosa. Pupa olive-green, head with sharp point, wing-cases keeled; thorax and last abdominal segment angled. Butterfly a swift flier, frequently returning to its starting-place

nicobarica. and only common in certain years. — **nicobarica** *Moore*, in general smaller and darker, but differing much less

hippo. from *hippoides* than the preceding. Nicobars. — **hippo** *Cr.*, a very distinctive form, rarely represented in collections, the ♂♂ of which approach *enarete Bdv.* from Borneo beneath in having the black-brown distal margin of the forewing widened to beyond the apex of the cell. ♀ with very broad white transverse bands on the fore-

hippona. wing; occurs in West Sumatra. — **hippona** *subsp. nov.* is the much smaller form from North-East Sumatra, always

with narrower black margins and in the ♀ also with reduced transverse bands. Dr. MARTIN saw the ♀♀ frequently rest on the same flowers, such as Udaiana cynis. — **purana** *subsp. nov.* Larger than *hippona*, ♂ more broadly *purana.*
and strongly marked with black, beneath lighter yellow. ♀ darker with broader white streaks. Island of Engano. —
A ♀-form, which occurs in all the island races from the Nicobars to Palawan and Formosa and which is
distinguished by olive- or moss-green-scaled upper surface and light or dark yellow instead of pale green tinge
on the upperside of the hindwing, I call **galbana** *form. nov.* — **vasava** *subsp. nov.* Likewise larger than *hippona*; *galbana. vasava.*
♂ beneath darker green than Indian *hippoides* and *hippona*; Malay Peninsula. — The larva of *hippona* lives on
a small bush which grows on the banks of rivers, superficially resembles that of *Catopsilia*, but is of more
slender shape. The pupa is however quite different, with stellate inpression on the thorax. The butterfly emerges
after about seven days and on Sumatra shows very little tendecy to seasonal dimorphism. — **enarete** *Bdv.* (58 e). *enarete.*
♂ more deeply and broadly marked than *enaretina*, beneath with black-brown distal margin extending to
the cell and as in *latifasciata* with black-scaled subcostal. ♀ scarcely different from those of the Malay Peninsula
and Sumatra; North and South Borneo. — **enaretina** *Fruhst.* (58 f). ♀ with pure white transverse bands on the *enaretina.*
forewing, sometimes with violet reflection. I have only specimens before me belonging to ab. *galbana*. Palawan,
Balabac, and according to SEMPER on some other small islands of the Philippines. — **andrea** *Eschsch.* (58 e). *andrea.*
♂ very similar to that of *enaretina*, but beneath with dark ochre-yellow tinge and uniform distal margin. The ♀
figured represents the form of the wet season, that of the dry season (= **aternia** *form. nov.*) has the cell of the *aternia.*
forewing almost entirely white, without the black transverse band at its apex. Larva on a species of Gynmo-
sporia; above green, beneath whitish, with black spiracles; on the dorsum four blackish dots. Thoracic legs
rose-coloured. Pupa grey, dotted with black, with pointed head, dorsal plate broad, with 3 black spots at
each side. In Manila the pupal stage lasted 8 days. Luzon, Mindoro (?). — **lepidana** *subsp. nov.* ♀ even lighter *lepidana.*
than that of *aternia*, with very narrow black distal margin to both wings. Under surface of the hindwing varying
from light yellow to deep yellow. Guimaras, Negros, Panay. — **formosana** *Wall.* (58 e), one of the most *formosana.*
variable local races, the ♂♂ of the dry season from the plains with almost white under surface to the hindwing,
on which the yellow is only very faintly indicated, whilst in the mountain form examples occur with dark
to ochre-yellow tinge. In the ♀ specimens with grey-white under surface predominate, whilst ab. *galbana* is
very rare. From the plains up to elevations of 5000 ft. Formosa[1]). — **inornata** *Moore*, of which only ♂♂ with *inornata.*
dark ochre-yellow underside to the hindwing are known, flies on Hainan. — With the name-typical subspecies
lyncida *Cr.*, from Java, begins the series of those island races whose ♂♂ have the hindwing pure white beneath *lyncida.*
also; only very rarely in West Java occur atavistic specimens with the hindwing suffused with light yellow. The
butterfly is common everywhere in Java up to elevations of 3000 ft. As long ago as 1791 STOLL knew and described
the dark green larva ornamented with yellow-green rings and black hairs, and also the light yellow, black-dotted
pupa, which after 8 days assumes a red-brown colour, and from which the butterfly emerges after 8 days. Accord-
ing to him it lives on the cotton tree. The ♀ has above broad whitish yellow transverse stripes. An aber-
ration with yellow areas above (f. **lurida** *form. nov.*) is rare; it also occurs in India. Java, Bali. — On the island *lurida.*
of Bawean, very close to Java, the ♀ is already essentially darker: = **fabiola** *Fruhst.* (58 d). — On Lombok *fabiola.*
occurs a very interesting race, **icilia** *form. nov.*, with beautiful light yellow transverse streaks and basal area on *icilia.*
the hindwing in the ♀♀, whilst the under surface is grey-violet with the exception of the broadly yellow costal
margin. Ascending from the plain to 2000 ft. Very common in April and May, a true „campong" (village)
butterfly, which prefers to fly along the roadside and garden-hedges and during the hot day-time also remains
at the edges of woods close to the ground. — **papissa** *subsp. nov.* is larger than the preceding and more broadly *papissa.*
margined with black. Sumbawa. — **floresiana** *Btlr.* (58 e), with both sexes very narrowly margined with black *floresiana.*
and bearing dark yellow areas on the upper surfare of both wings; Flores, Alor, Sumba (?). — **dohertiella** *Btlr.* (59a) *dohertiella.*
is a modified, very small form, with sharply defined deep black distal margin to both wings, large whitish
distal areas lightly dusted over with grey on both wings and almost pure white under surface to the hindwing
in the ♀♀; Wetter. — **lynceola** *Fldr.* (= timorensis *Btlr.*), with broader and yellowish stripes in the ♀♀; Timor. — *lynceola.*
lycaste *Fldr.* (58 f, only fig. 1) inhabits southern Celebes. The ♀ has white discal patches on the forewing and *lycaste.*
a lighter basal area on the hindwing, as in *formosana.* — In North and East Celebes there is a race with the ♀♀
entirely black above (58 f, fig. 2), which I now call **gellia**; the ♂♂ differ from those of *lycaste* from the south *gellia.*
of the island in having the black distal margin of both wings twice as broad. — **lutatia** *subsp. nov.*, from the *lutatia.*
island of Tana Djampea to the south of Celebes, is a very interesting race, being quite isolated, on account
of the yellow underside of the hindwing, among the forms of the neighbouring islands, whose ♂♂ without
pxception show a white hindwing. In the ♂♂ the black distal margin of the hindwing above is a little more strongly
ɔentate than in *gellia*-♂♂.

On the Moluccas and in the Papuan region *lyncida* is represented by **A. ada,** which is distributed to the Carolines, Mariannes and Solomons. There are already 15 island forms known, and without doubt a large number still remain to be discovered. As in *lyncida* there also occur in its Papuan sister-species ♀♀ with yellow and others with grey basal half to the hindwing beneath. But the latter appear to occur in inverse proportion, i. e. more

[1]) cf. addenda.

cana. rarely (forma **cana** 59 f). — In almost all the island races we meet with a further form (that of the dry season?)
tristitia. without or with very little black colour on the distal half of the hindwing above (f. **tristitia** *form. nov.*). Larva
ada. unknown, as well as details concernig the habits. The name-type from the South Moluccas is called **ada** *Cr.* (59 f),
leucosticta. not very rare on Ceram, Amboina and Saparua. — BUTLER has separated as **leucosticta** the form from Buru, which is unknown to me in nature, but is perhaps identical with specimens which I have before me from Obi, and which
stenia. bear a white instead of yellow apical spot on the underside of the forewing; a very inconstant character. — **stenia** *Fruhst.* is a rarer race with broad grey submarginal spots on the upper surface, showing through from beneath, very large, but nevertheless with only narrow black distal margin. The whole apical area and almost the entire cell of the forewing deep black, with a very large white subapical spot and a still broader quadrate white spot at the end of the cell. Hindwing light yellow with orange-coloured tinge at the proximal edge of the very uniform terminal band, which extends to the terminal margin and is distally ornamented with yellowish fringes.
bandana. Locality unknown; probably Halmaheira. — **bandana** *subsp. nov.* approximates to *ada*, but with narrower black
cilla. distal margin to the hindwing beneath and richer orange-coloured tinge. Banda. — **cilla** *Fldr.* (59 f) is the race
clavis. inhabiting the Aru Islands and **clavis** *Wall.* (60 a) the very similar form from the Key Islands, which has the
thasia. characteristics of the dry-season-forms, but reduced black margins. — **thasia** *Fruhst.* (60 a), with relatively broad distal margin in the ♂♂ and narrower black discal area in the ♀♀, has the distal margin of the forewing in the ♀♀ broken up into streaks and beneath very slight orange tint. Type from the island of Roon, also known from
nerva. Mafor and Dutch New Guinea. — **nerva** *subsp. nov.* has the black distal margin in the ♂♂ somewhat narrower again; the darker ♀♀ more uniformly margined with black and more extended orange tinge on the hindwing
herennia. beneath. Waigeu, Salawatti. — **herennia** *subsp. nov.* has the ♀♀ above of the deepest and most beautiful greenish yellow and beneath of the richest orange-colour. Moreover the apical spot of the forewing beneath in the ♂♂ is
plotina. reddish instead of light yellow or white. British New Guinea; North Australia: Cairns. — **plotina** *Fruhst.*, with the upper surface of the ♀♀ almost pure white, has the hindwing beneath almost entirely orange-coloured in
solstitialis. both sexes. Fergusson Island. — **solstitialis** *Btlr.* is a race without the black subapical transverse band on the forewing, a characteristic which is common to all the branches of *ada* from the Solomons. The black marginal
florentia. band of the hindwing only moderately broad. New Pomerania. — **florentia** *Gr.-Sm.*, from Guadalcanar (Solomons), has beneath a short black distal area on the hindwing, only extending to the lower radial, which is proxim-
vana. ally bordered by a large, quadrate orange-coloured spot. — **vana** *Fruhst.* is the most brightly coloured form known. Hindwing anteriorly light sulphur-yellow to the middle of the cell, and then gradually changing into a fiery orange. The black-brown marginal area becomes lighter distally and is ornamented with golden-brown
ribbei. scales. Bougainville. — **ribbei** *Fruhst.*, from New Georgia, is again duller-coloured with broad, uniformly black-brown distal area on the underside of the hindwing, which posteriorly is only margined with orange for a short
monna. distance. — **monna** *Fruhst.*, from the Solomons, without exact locality, appears to approach *solstitialis Btlr.* and has like the latter a very narrow black marginal border to the hindwing, especially above. *monna* further differs both from *ribbei* and from *vana* in the very narrow black apical tinge on the forewing. The under surface of the hindwing is characterised by the light sulphur-yellow ground-colour, in which all the basal and apical orange is absent. Only in the anal angle a very narrow reddish yellow shade is noticeable, whilst according
ardens. to BUTLER *solstitialis* shows a still more extended orange area than *florentia*. — **ardens** *Btlr.* (60 a, b), from the Mariannes and Pelew Islands, is one of the smallest *ada*-races; the ♂ beneath dull yellow, ♀ dull grey with the
ella. distal margin of the forewing sharply dentate proximally. — Finally, **ella** *Btlr.*, from the island of Yap (Carolines). is again somewhat more brightly coloured, with the whole of the black distal area of the hindwing narrowly bordered with the orange colour.

A. nero with its vivid red introduces a bright element into this otherwise dull-coloured genus and is the only bright red butterfly of Asia except a few of the Lycaenids. In spite of the wide distribution of the species and its abundance nothing is known as to the life-history. *nero* is a rapid flier, which is occasionally met with on sunny paths in the woods, where it is said to have a certain resemblance to withered leaves on account of the undecided colour of its under surface. FORBES even observed that amorous ♂♂ took leaves driven slowly by the wind for ♀♀ and swarmed round them to no purpose. In Java I observed large crowds of *nero* at puddles in the primeval forest, at which both sexes appeared together, to suck up the moisture in company with
hainanensis. *Saletara panda.* — **hainanensis** *Fruhst.* (58 c) is the most northerly of the local forms; it very nearly
galba. approaches **galba** *Wall.*, from North India, Burma and Tonkin, of which **nebo** *Gr.-Sm.* represents a light yellow
nebo. dry-season-form. Rare in Sikkim and Tonkin, at the extreme limit of its range, *galba* occurs very commonly
figulina. in Assam and Burma. In Sumatra and the Malay Peninsula appears **figulina** *Btlr.* (58 c), a black race, especially in the female, which extends northwards to Tenasserim, where it passes gradually into *galba*. In all the island forms there occur, though very rarely, light yellow or pale red specimens, such as the ♂ figured under 58 b
ramosa. as *figulina*, which may be distinguished as forma *sufflava form. nov.* — **ramosa** *Fruhst.* differs from the general type in the black-dusted interneural areas of the forewing above; Nias; an appearance which is repeated, though
neronis. in a weaker form, in **neronis** *Fruhst.*, from the island of Kangean. — On the Batu Islands, south-west of Sumatra,
pulonus. flies a form of which the ♀ with its light red upper surface somewhat recalls Javan specimens: this is **pulonus**
nero. *Fruhst.*, from Pulo Tello. — **nero** *F.*, from Java to Bali, is the first-known subspecies; the ♀♀ bear in the disc

of the forewing an isolated black spot instead of a band coincident with the discocellular as in *figulina*. Both sexes vary only in the more extended or denser black dusting of the under surface. In the whole of Java, up to elevations of 2000 ft. — **baweana** *Fruhst.* (58 b) is a distinct local form, which has become differentiated on the small island of Bawean in spite of the short distance from Java, and whose ♀♀ more nearly approach the Celebes race than any other form of the Macromalayan region. There is also a darker ♀ than the one figured, with only 2 red discal patches on the forewing. There also occur on Bawean, as in all the places where *nero* is found, light and dark red specimens (on 58 b, third and fourth figure). The dark red specimens have mostly been longer on the wing than the light ♂♂. — **chelidon** *Fruhst.* ♂: upper surface of the forewing dusted with black much as in *ramosa*, larger than Javan specimens; ♀ with the black distal margin of both wings almost twice as broad as in *figulina*-♀♀; North and South Borneo. — **flavius** *Gr.-Sm.* is a much lighter form, light red-yellow in the female, with narrow black margins; Taganac Islands, north of Borneo. — **palawanica** *Stgr.* has in the male only very little black dusting on the forewing. Of the ♀ there are 3 forms: one similar to the ♂; a second, **coelita** *Fruhst.* (58 c), with white-blue median area; and thirdly **helvola** with light yellow-red disc and submarginal spots of the same colour. Palawan, common in January. — On the Philippines occur races which collectively are characterised by a broad black, sharply defined distal margin. The broad central area varies in colour from light yellow to orange. The darkest of the known races is **zamboanga** *Fldr.*, from Mindanao, the ♂ of which has been described by Butler as *mindanensis* — **soranus** *subsp. nov.* is based upon specimens from Cebu, whose ♀ has the central area, which is white on the forewing and yellow on the hindwing, twice as broad as in South Philippine ♀♀. — **domitia** *Fldr.* (♂ = asterope *Fldr.*) is a form with narrow black distal margin, which is mostly dark red in the male and commonly almost white in the female; North Philippines, Luzon. — **tibericus** *subsp. nov.* (♀ by an oversight described on pl. 60 f as *mariae*) is a light vermilion form with the distal margin of both wings in the ♂♂ finely dusted with black, less interneural scaling on the forewing and broad black discal bands on the hindwing beneath. Bazilan, February-March. — This form approaches the somewhat smaller **acuminata** *Snell.* in the copious black dusting of the forewing and a brown-black submarginal band which traverses the whole of the under surface of both wings. Tana Djampea, south of Celebes, flies in December. — With **zarinda** *Bdv.* (58 c) begins a series of forms which are conspicuous by the falcate, very pointed shape of the forewing and the absence of the black vein-colouring on both wings. 58 c, first figure, represents an aberrant ♂ with the veins on the forewing slightly tinged with black distally. Two forms of the ♀ are known, one with red median bands and submarginal spots on the upper surface and the other with these markings white: f. **fatima** *Voll.* (58 c). The ♀♀ of *zarinda* have a more extended black-grey tinge beneath than the other races. — In South Celebes occurs an aberration of the ♂ with light yellow wings; this is ab. **aurosa** *Fruhst.* As is the case with *nero*, I also observed in Central Celebes that the ♂♂ settled in dense crowds on moist sand-banks or on mud-banks in the river. — **phestus** *Westw.* is a small dark form from the attendant island of Talisse, North Celebes. — **sulana** *Fruhst.* is a large form with darker underside from the Sula Islands. — Finally, **bouruensis** *Wall.* is a race very similar to *zarinda* in the male, but with light vermilion ♀, which differs from all the allied forms in a narrow deep black basal area and a continuous light red-yellow submarginal band on both wings. Doherty also discovered a ♀-form with white discal area on both wings, analogous to *fatima Voll.* from Celebes. Kühn found the species not rare in eastern Ceram.

baweana. *chelidon.* *flavius.* *palawanica.* *coelita.* *helvola.* *zamboanga.* *soranus.* *domitia.* *tibericus.* *acuminata.* *zarinda.* *fatima.* *aurosa.* *phestus.* *sulana.* *bouruensis.*

Where on the Moluccas the red *nero* disappears, occurs a representative of chocolate-brown ground-colour, **A. placidia** *Stoll* (60 e). In this species the ♀ is not dichromatic, but coloured like the ♂ (60 e), with a few washed-out yellow submarginal spots on the forewing. Amboina, Ceram. — On the North Moluccas, Batjan, Halmaheira and Obi, flies a local form, **maculata** *Stgr.*, which is distinguished in the female by somewhat more intensive yellow spots on the forewing.

placidia. *maculata.*

In the Papuan region the brown species disappears and in its place occurs as representative of the Indo-Malayan *nero* a blue-grey-scaled collective species with partly polychromatic ♀♀, of which **A. celestina** *Bdv.*(61d), from Waigeu, must be regarded as the name-type. Of all the races of *celestina* there are ♀♀ with whitish central area on both wings (**lileia** *form. nov.*) and others with the central area yellowish (**aurifera** *Fruhst.*, 61 e). — The subspecies which is most brightly coloured beneath we meet with on the Aru Islands; it is **barea** *subsp. nov.*: ♂ above with narrow black transcellular band; under surface for the most part brilliant lemon-yellow, tinged with canary-yellow, especially on the hindwing. ♀ above either white or light orange-yellow (= **flava** *Ribbe*). — **galepsus** *subsp. nov.* (61 e), with stronger submarginal bands on the forewing and broader black distal margin to the hindwing; the ♂ is characterised beneath by a sand-grey tinge on the apical part of the forewing and the whole of the hindwing. Key Islands. — **sekarensis** *Ribbe* (61 d) has in the male only a narrow black distal border on the upperside of the forewing, without a trace of a submarginal spot, and a broad grey tinge on the underside. The ♀ approximates to that of *celestina*; the basal half of the hindwing is, however, mostly yellow-brown instead of whitish. A ♀-form from Kapaur with grey-yellow tinge on the hindwing I call **limia** *form nov.* Dutch South and West New Guinea. — In German New Guinea occurs a specialised race, **galerus** *subsp. nov.* (61 d), with light blue upper surface in the ♂♂, which beneath assume a whitish blue colour, without the least tinge

celestina. *lileia.* *aurifera.* *barea.* *flava.* *galepsus.* *sekarensis.* *limia.* *galerus.*

of grey-brown. The ♀ is beneath likewise very light, forewing with broad black submarginal band, but with white instead of black tone. Hindwing without black distal band, which, however, shows through distinctly from the upper surface. According to HAGEN drinking at the gravelly, shady banks of brooks, on moist sand, and not rare. — **delicata** *Btlr.* very nearly approaches *celestina*; but it is above darker blue and beneath has the submarginal band narrow but traversing the whole of the forewing. New Pomerania. — **eumelis** *Bdv.* probably also belongs here; the description: „Forewing white, the base black and also the costa and apex; hindwing white with broad black marginal band, beneath at the median saffron-yellow" seems to refer to a ♀. New Mecklenburg. — **korridona** *Gr.-Sm.*, only the ♀ known, with yellowish white upper surface, has a very broad brown-black distal margin to both wings and the apex of the forewing beneath is tinged with purple-white, the band of the hindwing covers a third of the upper surface and has a slight blue-red sheen. *Korrido* on the island of Mysore.

delicata. *eumelis.* *korridona.*

A. asteria *Misk.* (= cerussa *Fruhst.*) (61 e) is a sharply separated species, in the ♀ with still stronger black bands on the upper surface. Beneath in both sexes a saffron-yellow tinge fills up the whole cell of the forewing. Hindwing of the ♂ uniformly light grey, that of the ♀ grey-violet with black-brown median band. Queensland.

asteria.

A. clementina is a small species, of which only two races are known: **agar** *Fruhst.* (61 e). ♂ beneath with blue-grey basal area on the forewing and smoke-brown apex, the underside of the hindwing also smoke-brown; ♀ beneath grey-violet with black submarginal bands on both wings. The rainy-season-form of the ♂♂ is darker blue-grey than the figured dry-season-form. Dammer, Babber, Tenimber. — **clementina** *Fldr.* has a purer white ♀ with narrower black longitudinal bands. Amboina; is said also to occur in Australia.

agar. *clementina.*

A. ithome *Fldr.* (60 b), with black wings, which have a broad vermilion median band on the upper surface and are lighter yellow beneath as far as the base, occurs only in Celebes. The ♀ recalls *Huphina affinis* (58 b) in the dull grey-white median band. I found *ithome* at the edge of the forests on the coast of Toli-Toli in November and December drinking at dirty places by the road, and Dr. MARTIN even took it in the immediate neighbourhood of Macassar.

ithome.

A. nephele belongs exclusively to the Philippines, where the species as one proceeds from north to south presents a striking example of the tendency of many Pierids of the Philippine Archipelago to assume a more melanotic colouring in the south than in the north and north-west. — **nephele** *Hew.*, from Luzon, is traversed by very broad white bands on the forewing, which on the hindwing of the ♀ are replaced by yellow ones, with orange-coloured bordering to the narrow black distal margin. — In **invitabilis** *subsp. nov.*, from Mindoro, the white median areas are narrower and in the ♀ there is a grey-white instead of a yellow basal area. — In **aufidia** *subsp. nov.*, from Bazilan, the bands are still narrower, but the ♀ has a yellow basal area on the hindwing. — In Mindanao the basal area of the hindwing in the ♀♀ is darkened and the white band of the forewing in the ♀♀ is only a few millimeters in width, hence the black distal margin is extended, = **elis** *subsp. nov.* — According to SEMPER the melanotic darkening reaches its maximum on the Sulu Islands, where **hostilia** *subsp. nov.* occurs, with the black distal margin of both wings twice as broad as in Luzon specimens. — Finally, **dilutior** *Stgr.* (59 f) must be regarded as a lighter form, in which in the ♀♀ the basal area of the forewing in many specimens begins to be broken up into brown atoms, and the black distal margin in both sexes is still narrower than even in *nephele* from Luzon.

nephele. *invitabilis.* *aufidia.* *elis.* *hostilia.* *dilutior.*

With **A. indra** begins a series of forms which by some authors have been grouped together under the untenable generic name *Hyposcritia Hbn.* In it and its allies we observe the maximum of climatic influence, which affects the colouring and pattern as well as the size; moreover, there occurs extreme sexual dimorphism in colours, forms of the hot valleys and rain-laden mountains, and insular isolation, so that the specific identity of the forms was formerly not known and many were erected as separate species. The rainy-season-form **indra** *Moore* (59 a) has in Sikkim specimens a pure white colour, in the larger Assam examples a yellowish tone, which in **mahana** *Moore* (= imbecilis *Moore*) (59 a) becomes sand-coloured, and also the black apical spot on the upper surface begins to be broken up. The ♀ is extremely rare, scarcely one to 1000 ♂♂, above almost entirely black, with grey-scaled, white discal area on the forewing, beneath with very broad black transverse band on the forewing and greenish yellow tinge on the hindwing. The species only very rarely migrates into the Bengal plain, but is common in Sikkim, Assam and Burma at elevations of 1000—4000 ft. — In the Indian plague-district near Poona, north of Bombay, occurs a small subspecies, with very pointed forewing: **shiva** *Swinh.* (59 d). — In South India, in Travancore and the Nilghiris, there is a form with somewhat broader black

indra. *mahana.* *shiva.*

apical spot on the forewing, **statilia** *subsp. nov.*, figured as *narendra* on pl. 59 d. But the latter name designates exclusively the distinct race from Ceylon, where **narendra** *Moore* occurs very rarely at elevations of from 2—4000 ft. and has the under surface of the hindwing beautifully marked with dark yellow-grey. — **thronion** *subsp. nov.*, from Siam, above like *indra* from Sikkim, differs beneath by a broad black subapical band on the forewing and thin red-brown transverse bands on the hindwing. Found in February drinking with closed wings on wet sand-banks at the edges of rivers. Here belong probably also specimens from Annam and Tonkin. — **menandrus** *subsp. nov.* is a larger island race, with lighter underside to the hindwing, only lightly marbled with red-brown, and the subapical band of the forewing narrower and more broken. Hainan. — **aristoxemus** *Fruhst.* (50 f) is a seasonally dimorphic and highly specialised island form; ♂ above as *indra*, apex of the forewing and the surface of the hindwing beneath yellow, sprinkled with dense brown scales; ♀ above with black dot at the apex of the cell of the forewing, hindwing with light green basal area and long black teeth to the distal margin. Flies in May, in the mountains of Formosa. — **thrasea** *form. nov.* (50 e and f) is the form of the plains, occurring in July and August, with light grey under surface recalling *lucasi* from Java. ♀ without black cell-spot, hindwing white with narrow black distal margin. Formosa.

statilia. *narendra.* *thronion.* *menandrus.* *aristoxemus.* *thrasea.*

A. lucasi *Wall.* (59 e), hitherto only known from the volcano Gedé in West Java, where the species occurs very rarely at an elevation of 4000 ft. The ♀ is above slightly yellowish, with black cell-dot on the forewing, otherwise like the *thrasea*-♀, only deeper black.

lucasi.

A. nupta *Fruhst.* (60 e), which I formerly took for a *paulina*-race, I think should also be inserted here. Under surface as upper, only with the apical area on the forewing and the whole hindwing yellowish. Very rare; only one specimen known, in my collection. Nias.

nupta.

A. lalage *Dbl.* (59 b) is even more variable than *indra* and even within the empire of India three races may be differentiated. — **durvasa** *Moore*, of which a ♂ of the dry-season form is figured 59 b (third figure), an intermediate form as *pseudolalage Moore* 59 a and a ♂ of the rainy-season form from Sikkim 59 b (first figure). The hindwing of the dry-season form is beneath whitish or grey, that of the rainy-season form yellow. The very rare ♀♀ have in the form of the dry season a white upper surface with mother-of-pearl gloss on the basal area and very broad black apical border. The distal margin of the hindwing only lightly spotted with black. The under surface of the hindwing dark greyish sand-colour. This form is the only one which goes as far as the West Himalayas. In Nepal and Sikkim the rare ♀♀ ascend to 10,000 ft., whilst the common ♂♂ scarcely reach beyond 6000 ft. In the rainy-season form of the ♂♂ from Sikkim an aberration is not rare in which the black spot at the apex of the cell of the forewing is united with the black distal margin: = ab. **confluens** *nov.* — In Assam occurs the larger **lalage** *Dbl.*, whose extreme dry-season form is not distinguishable from the corresponding form of *durvasa* from Sikkim, but on the other hand the ♀-form with yellow under surface to the hindwing figured 59 b is never in my experience found in Sikkim; nor is the Assam intermediate form 59 b (second figure, under surface). The ♀ of *lalage* occurs also in the intermediate form with grey-white under surface and is not rare at times and moderately variable. Assam up to 6400 ft. — **argyridina** *Btlr.* is the third race, which recent English authors erroneously unite with *lalage*. The dry-season form is scarcely larger than *indra shiva Swinh.* and has the apex of the forewing and the hindwing dark grey beneath. The intermediate form has larger white subapical spots on the forewing. Burma and Siamese Shan States. — **mutina** *subsp. nov.* (59 c) has in the male a narrower black distal margin to the forewing. The white subapical spot of the ♀ is shorter and broader than in *lalage*; the basal area of the hindwing almost pure white, the distal border violet. Tonkin, rare in April at elevations of 4000 ft. — In **lageloides** *Crowl.* the black spot before the apex of the cell reaches to the base of the forewing and is distally confluent with the distal margin, enclosing a very broad white subapical spot. Under surface of the hindwing with red-brown undulate submarginal line. Hainan. — The species will pretty certainly yet be discovered also on Formosa. — At the point where *lalage* ceases in Burma, begins a race which closely approximates to *lageloides*, **lagela** *Moore*, with still broader black transverse band, which emanates from the cell of the forewing. Under surface somewhat darker than in *lucasi*, nearly approaching that of *pandione*. Lower Burma to Perak, taken at elevations of 3—6000 ft.

lalage. *durvasa.* *confluens.* *lalage.* *argyridina.* *mutina.* *lageloides.* *lagela.*

A. pandione is the Macromalayan continuation and representative of the continental *lalage*. Three island races are known. — **ozolia** *subsp. nov.* (59 c), whose ♂♂ often occur in hundreds on the plateaux of Sumatra, but whose ♀ is still unknown. — **whiteheadi** *Gr.-Sm.* is a larger race, with still broader black margins and smaller white subapical spots; under surface of the hindwing almost black-violet with yellowish costal area and an oblong patch at the apex of the cell. Kina Balu, North Borneo. — **pandione** *Hbn.* (59 c) is very common in all parts of Java at elevations of over 4000 ft. and is one of the first butterflies which the natives bring the collector, because it can be easily taken at puddles on the roads. Some ♂♂ have the upperside to both wings yellowish (form **eburnea**). The ♀ is rare, and may be recognised by the broader distal margin and the darker, violet-tinged under surface of the hindwing. I found *pandione* also in Lombok, on the plateau of Sambalun at a height of 4000 ft., hence it must also occur in Bali.

ozolia. *whiteheadi.* *pandione.* *eburnea.*

phoebe. **A. phoebe** *Fldr.* represents *lalage* on the Philippines. Three local forms are known; the type from Luzon: forewing with the apex broadly black, a large quadratic spot at the apex of the cell and two white submarginal spots Hindwing without a trace of a border. Under surface whitish yellow, often also
montana. grey-sand-coloured. — **montana** *Rothsch.* is a very fine mountain form, taken at an elevation of 6—7000 ft.
zamorra. on the island of Negros, beneath dark yellow with the black spots of the forewing broader — **zamorra** *Fldr.*, with three large white subapical spots on the forewing and beneath with the black markings reduced. Mindoro.

lalassis. **A. lalassis** *Gr.-Sm.*, a very interesting local species, on which NICÉVILLE has erected the „genus" *Lade* on account of the absence of the anal pencil of the ♂♂; occurs only in Lower Burma and Perak. —
indroides. **indroides** *Honr.*, with broader black apex to the forewing, is the rainy-season form. Both resemble *lalage* with the black marking strongly reduced and the forewing still more pointed. Under surface of the hindwing yellowish with red-brown dusting.

The following species form a natural group, which is treated by English authors as a separate genus under the old Hübnerian name „Catophaga". But the neuration does not at all justify the separation and as moreover quite a number of new names have to be introduced for forms of this variable butterfly, we are glad to drop a name.

A. albina is a dimorphic species, distributed from Anterior India to the Moluccas and Philippines, in which the ♂♂ do not vary at all locally. But the ♀♀ are polychromatic. with a tendency to the formation of horodimorphic and individual forms, as well as insular races, which are all connected by transitions. On pl. 60 c and d we represent 11 ♀♀-forms and still without exhausting all that are known. The ♀♀ are most constant on the continent, where 3 forms predominate, whilst on the islands, especially in Micromalaya, a bewildering variety has been observed. Larva found in South India on Hemicyclia venusta, a Euphorbiacea, of a light green colour with yellowish white longitudinal bands, ornamented with very fine hairs. Pupa dirty white to greenish, with black dots, broadest in the middle with 2 wing-like processes. Butterfly locally common, according to my experience exclusively frequenting flowers, occurring all the year round, but, e. g. on Lombok, sometimes suddenly appearing in immense numbers. They are particularly fond of scabious, are by no means shy and allow themselves to be taken with the fingers. Elevations of from 2—4000 ft. are specially favoured by them, but they are also met with in the hot plains at the edges of woods and even in gardens, for instance at Haiphong in Tonkin in company with *Papilio helenus*, as one of the first butterflies when in March the winter mists begin to disperse. Uncus long, scalpel-shaped, without dorsal thickening, medially widened, distally with obtuse point. Valve broad, with long hairs, sack-shaped, distally ovally rounded. The valve of the island races broader than that of the conti-

confusa. nental subspecies. — With **confusa** *nom. nov.* (= darada *auct.* nec *Fldr.*) (60 d, as *darada*) begins the most northerly branch of this collective species, in which the ♂♂ of the rainy-season form are occasionally slightly tinged with black at the apex of the forewing. Two forms of the ♀, which are found wherever
principalis. *albina* occurs: ♀-f. **principalis** *form. nov.*, beneath blue-white, markings as above without the black distal border
semiflava. of the hindwing; predominates in the dry season. ♀-f. **semiflava** *form. nov.*; apex of the forewing and the whole of the hindwing pale ochre-yellow. *confusa* is rare in Sikkim, common in Assam, Siam and
swinhoei. Tonkin. — **swinhoei** *Moore.* ♀ above with the black distal margin of the hindwing somewhat narrower and
venusta. more broken up. South India. The larva full-fed in 13 days, pupal stage lasts 9 days. — **venusta** *Moore*,
flava. from Ceylon, with 4 ♀-forms, of which the third (60 d, as *neombo*) must bear the name of **flava** *Röb.*, with the under surface of the forewing entirely yellow. Together with it occurs also on the island the ♀ with white under surface and ♀-form *semiflava*. *venusta* is common everywhere in Ceylon in the first months of the year, between 2 and 4000 ft. at open places in the woods, and participates in the annual migrating swarms in company with *A. paulina Cr.* — In East Java, Bawean and on the small Sunda Islands flies
micromalayana. a race, **micromalayana** *subsp. nov.*, whose ♀♀ occur in as many as 10—12 forms. The normal ♀♀ are as a rule only narrowly margined with black. In addition there are ♀♀ exactly like the ♂, en-
virilis. tirely white (second figure) except for the black distal margin: this is **virilis** *form. nov.* (60 c ♀).
punctata. A commoner form has a black dot between the anterior extremities of the medians (ab. **punctata,** 60 c, third figure). When this dot is connected by fine black lines with the distal margin we have ab.
ambigua. **ambigua** *Gr.-Sm.* (60 c, sixth figure). A ♀-form with the forewing dusted with grey throughout I have
saweloides. described as **saweloides** (60 c); these are rare and only occur on Lombok and Sumbawa. The type from the latter island is much darker even than the ♀ figured from Lombok. ♀♀ with sharply defined, broad,
agatha. uniform black distal margin are called **agatha** *Stgr.* (60 d); described from Palawan, but also in my col-
umbratilis. lection from Bawean to the islands of the Teninber Group. — **umbratilis** *Fruhst.* has the same distribution of the black bands, but an ochre-yellow instead of white basal area on the hindwing beneath; from Lom-
citronella. bok, rare. The same form, but with the basal areas of both wings yellow above and beneath, is **citronella,**
citrina. *Fruhst.*, whilst 60 c (fifth figure) represents ♀-f. **citrina** *form. nov.*, yellow on both sides, in all intergrades from the form figured, which recalls *punctata*, to ♀-f. *flava*, with broad black subapical bands. Finally occurs a ♀-aberration corresponding to *punctata*, above white, beneath with light ochre-yellow apex to the
subochracea. forewing and hindwing of the same colour: this is **subochracea** *form. nov.* — The local race from Sumbawa
infuscata. is **infuscata** *subsp. nov.*; in this all the ♀-forms are essentially more broadly margined with black than the corresponding forms from Lombok, Wetter and Java. The specimens which resemble ♀-f. *flava* and ♀-f.

semiflava are darker ochre-yellow beneath than those forms. — **albina** *Bdv.* is the name-type from the South and North Moluccas, where the ♀♀ do not vary so much as in Micromalaya. — According to Ribbe, this species was very common at Illu on Ceram. Ribbe writes of it: „When I came to the river in the forenoon whole clouds of these insects flew up in alarm, they were to be found in thousands wherever there was running water. With one stroke of the net I once succeeded at a favourable spot in covering about 150 specimens. Unfortunately the ♀♀ were very rare." — **pancheia** *subsp. nov.* is the race from Palawan, with the cell of the forewing almost entirely black-brown, the upper surface of both wings finely powdered with black. Only 4 ♀-forms, namely *principalis, semiflava, neombo* and *agatha*, are known from Palawan, all of which fly in January. *albina* probably reappears on the South Philippines in races very similar to *pancheia*. — Boisduval has described a white and a yellow ♀-form of his **neombo;** the locality of this insect is uncertain, but according to a statement of Moore's is to be looked for in Sumatra or Borneo. The white form must naturally be regarded as the typical one, although the yellow form was figured by Moore in 1857 as *neombo*, from Ceylon, an error which I have only just discovered. Hence for the *neombo* of pl. 60 d must be substituted the name ♀-f. **flava** *Röber*, which occurs on all the islands from Ceylon to Palawan and Obi, although the other ♀-forms present local varieties, and the Macromalayan subspecies of *albina* must be called *neombo*. — **semperi** is the name given by Moore to the *albina*-race from the North Philippines, as figured by Semper. *albina.* *pancheia.* *neombo.* *flava.* *semperi.*

A. melania *F.* (61 c) has very much in common with *albina*, a wide distribution, numerous ♀-forms, its occurrence in large numbers; but it differs from it in the development of much more sharply separated local races, which are produced at very short distances, even within continental areas. The ♂ has always a relatively broad grey or black apical border, sometimes even a broad subapical reticulation or in its place some large diffuse spots, which are always absent in *albina*, the under surface is commonly orange- or ochre-yellow. Valve as in *albina*, but broader, shorter, rounder, the uncus short, more robust, with a dorsal median thickening. — **darada** *Fldr.* nec *Moore* is the name of the most northerly offshoot of this interesting species, which is rather rare in Sikkim, Assam and West China and only occurs sporadically (I have never been able to obtain a single ♀). — **adamsoni** *Moore* (61 a) is a local form from Burma, Tenasserim and Tonkin, distinguished by its dark ♀♀. — **pseudoleis** *subsp. nov.* (61 a), very common in Siam, is conspicuous by the broad black margins of the forewing and is characterised by a very light, partly yellow-tinted upper surface to the hindwing. In the dry-season form of the ♂♂ these black markings are almost entirely suppressed. — **distanti** *Moore*, from the Malay Peninsula, approaches it very closely, but the ♀♀ have broader margins. — **galathea** *Fldr.* (= roepstorffi *Moore*) (60 d) occurs only on the Nicobars and Andamans; an island race with the ♂ very little marked, yellow-tinted beneath; the ♀ appears to be still unknown, for what Moore figures as such in Lep. Ind. VII. t. 553 belongs to *albina* and its ♀-ab. *semiflava*. — **paulina** *Cr.* (vol. I, 20 g) occurs in Ceylon in two seasonal forms, that of the rainy season, beneath suffused with ochre-yellow, **lankapura** *Moore*; in addition a subordinate form with black submarginal band on the hindwing beneath: forma **fasciata** *form. nov.* (61 a as *lankapura*). The dry-season form **galene** *Fldr.* is light yellow beneath in the ♂, ♀ with white apex to the forewing and white under surface to the hindwing with mother-of-pearl gloss. Both are very common, but the early stages are still unknown. *paulina* occurs from the plains up to 6000 ft. mostly at the edges of woods and has a rapid and long-sustained flight. Sometimes perfect clouds of Pierids appear, composed half of *paulina*, which begin their flights on sunny days and towards their close drop down in large groups on wet places on the ground. — As **pione** *subsp. nov.* I designate the race from Sumatra, whose ♂ approaches the *leis*-♂ and *distanti Moore*. ♀ above essentially more broadly margined with brown-black than that of *leis*, hindwing recalling *sawela* by the dense grey-green dusting. Under surface of the forewing with yellowish apex, hindwing yellow with prominent, sharply developed, dark brown submarginal band, distal margin powdered with brown. — **leis** *Hbn.* (60 f) occurs only on Java. The ♂♂ (60 f) differ but little in the extent of the black apical colour on the forewing, but the ♀ occurs in many forms, one of which is here described as new. The typical *leis*-♀♀ are white beneath, with mother-of-pearl gloss, without black distal margin to the hindwing. ♀-f. **obscurior** *nov.* (60 e, f) the same, but with black distal margin to the hindwing; occurs also with whitish-tinged apex to the forewing beneath or with the black distal margin variegated with yellow. East and West Java, common up to elevations of 2000 ft.; Bawean, rare. — In Borneo, however, the species is very much modified, the most broadly black-margined ♀♀ occurring there: this is **athena** *Fruhst.* (61 b). I possess only ♀♀ with ochre-yellow underside to the hindwing, some with sharply expressed black-brown marginal bands, others with these bands powdered over with yellow. ♂ above more copiously ornamented with black than that of *leis*. Kina Balu. — **sawela** *Fruhst.* (61 b, c) is a considerably modified geographical race. ♂ with a distal row of black teeth on the forewing, beneath yellowish white with round black subapical spot. Of the ♀ scarcely two specimens are alike, and besides the figured principal form (61 c) there are also examples with the forewing almost completely black and the hindwing dusted over with blue-grey (f. **furia** *form. nov.*). The colour of the under surface varies from light lemon- to dark orange-yellow, with broad red-brown distal margin to the hindwing, which is sometimes variegated by yellowish sagittate spots, but is mostly absent or is replaced by a strongly curved *melania.* *darada.* *adamsoni.* *pseudoleis.* *distanti.* *galathea.* *paulina.* *lankapura.* *fasciata.* *galene.* *pione.* *leis.* *obscurior.* *athena.* *sawela.* *furia.*

submarginal band, as in our figure (61 c). I took my first specimens of *sawela* on the 25. May 1896 on Lombok, some weeks after the end of the rainy season, quite unexpectedly in the middle of the day between 1 and 3 o'clock, the butterflies settling on scabious flowers in company with *Appias albina*, sometimes 5 on one flower, much as we occasionally find *Argynnis pales* in similar clusters in the Engadine. The butterflies can then be taken up with the fingers. — In Sumbawa the black sagittate marking on the forewing of the ♂♂ is enlarged and extends also onto the hindwing, likewise the black and blue-grey dusting of
tambora. the ♀♀ is increased; this is **tambora** *Fruhst.* (61 c). — In the Micromalayan district and the Papuan
emilia. region we find further a whole series of *melania*-races. On Sumba we meet with **emilia** *Fruhst.* ♀ approaching *sawela* in size, but differing from this and *tambora* in having the white apical spots of the forewing much widened, so that they form a continuous band. The ground-colour of both wings is moreover purer
paula. white and more extended, the hindwing is more narrowly margined with black. — **paula** *Röb.*, from Wetter, is a very small race. ♂ with minute dentition on the forewing, ♀ with very narrow, sharply defined distal margin to both wings and small yellow subapical patches on the forewing. Entire under
eurosundana. surface of the forewing suffused with yellow. — **eurosundana** *Gr.-Sm.* ♂ almost without black markings on the forewing, ♀ like that of *paula* with yellow basal area to the forewing. Under surface almost like the
urania. ♀ of *sawela*, only smaller. Timor. — **urania** *Wall.* is a very distinct race. ♂ similar to *zoë*, but with more extended black areas on the forewing in the rainy-season form, without a trace of subapical spots in
albata. the dry-season form (= **albata** *Hopffr.*). ♀ (= *dohertyi Rothsch.*) beneath similar to that of *lankapura Moore*, but lighter yellow with still broader black subapical band on the forewing. Upperside of both wings black with white discal area on the forewing, yellow on the hindwing. Both sexes very rare in
zoë. Celebes, ♀ first discovered by Doherty. — **zoë** *Voll.* (61 b) differs from all the known races in having always two quadrate black subapical spots on the forewing of the ♂♂ beneath. In the rainy-season form
uranides. **uranides** *form. nov.*, which corresponds to *urania Wall.* from North Celebes, these spots are united by a narrow black band and the apical tinge of the forewing as well as the under surface of the hindwing are ochreous instead of light sulphur-yellow. Of the ♀, in addition to the form *principalis* with the hindwing
limbata. yellowish white beneath, may be mentioned further a form **limbata** *form. nov.*, with broad black distal
melanides. margin to the hindwing, and a form **melanides** *form. nov.* The latter is very similar to *melania F.*, but with still narrower black distal margin and whitish instead of ochre-yellow basal area to the hindwing. Such ♀♀ have misled English authors into sinking *zoë* as a synonym of *melania F.* and recording *melania* as
cynisca. occurring also on the Moluccas. Batjan, Halmaheira, Obi, not rare. — **cynisca** *Wall.*, very similar in the female to *zoë*, but with narrower white discal area to both wings and light yellow-green instead of ochre-yellow basal area and brown-black distal margin, not marbled with yellow, on the under surface of the
antoniae. hindwing. ♂ as in *albata Hopffr.* from Celebes. Buru, rare. — **antoniae** *subsp. nov.* is lighter than the preceding. Subapical spots of the forewing larger, yellowish. ♀ with narrower black distal margin, basal
saina. area of the hindwing light yellow. East Ceram, Saparoea. — **saina** *Gr.-Sm.* is a rare subspecies found in New Guinea. ♂ similar to *melania* and *zoë*, but with less black. ♀ similar to that of *zoë*, but with yellow instead of black apex to the forewing and ochre-yellow basal area on the hindwing beneath. Dutch
falcidia. New Guinea. — **falcidia** *subsp. nov.* is a still darker island race; ♀ with very large white subapical spots on the forewing, hindwing beautiful light yellow with a very broad black distal margin which is powdered
melania. over with yellow. Island of Biak, in Geelvink Bay. — **melania** *F.* (= ega *Bdv.*) (61 c, d) is the Australian form of this widely distributed species and varies very little. All the ♀♀ give the impression of occurring only in the rainy season: the upper surface is dazzlingly white with deep black borders, the under surface of the forewing pure white. Apex with blue-violet sheen, hindwing yellowish with red-orange-coloured
jacquinoti costal and anal margins. Australia, from Cape York to Sydney. — Of **jacquinoti** *Luc.* (♂ = athama *Luc.*), ♀ described from Balau (Palau?), English authors have erroneously referred the ♂ to Ceram, the ♀ to Samoa. The latter may possibly be correct. ♂ smaller than that of *melania*, above yellowish white, costa and apex finely margined with brown, beneath pale yellow with large yellow apical spot on the forewing. ♀ above yellowish white, with broad black margin and 3 yellowish subapical spots. Forewing beneath sulphur-yellow, with brownish apex, hindwing yellow, with broad black distal margin powdered over with
wallacei. pearl-grey. — **wallacei** *Btlr.* is a well defined island race; ♂ above pure white and with black-brown costal margin, ♀ of a beautiful dark lemon-yellow, forewing with broad black distal margin, which is moderately incised distally and bears three yellow patches. Terminal margin of the hindwing yellow, submarginal band
calidonica. uniformly black. Mallicollo Island, in the New Hebrides. — Felder has described as **calidonica** a race
psyche. from New Caledonia nearly allied to *wallacei*, of which **psyche** *Fldr.* is probably only the ♂. — Under the
agave. name *agave* passes a whole series of island races, of which the typical form **agave** *Fldr.* (61 b) bears a relatively broad black distal margin on the hindwing of the ♀, the forewing being always white. The colour of the hindwing varies from pale ochre-yellow to light lemon-yellow, and also sometimes remains
nikomedeia. white. Luzon. — As **nikomedeia** *subsp. nov.* I designate the race from Bazilan; ♂ with extended blackish apical margin to the forewing, and darker yellow under surface to the forewing than *agave Fldr.* from Luzon, ♀ white, with broad black distal margin, which has a violet sheen on the hindwing beneath.
terentilia. Similar ♀♀ occur also on Mindanao. — As **terentilia** *subsp. nov.* I describe the Palawan race, whose ♀♀

undergo a large number of modifications. ♀-f. **iria** *form. nov.* (61 b), above white, with isolated, rounded, brown discal patches on the hindwing; beneath, the apex of the forewing and the hindwing ochre-yellow without a trace of bands or borders. ♀-f. **flaminia** *form. nov.* has the hindwing similarly marked, but is above yellow, as are the subapical spots of the forewing. **horatia** *form. nov.* has yellow upper surface to the hindwing, which bears a broad black distal margin on both sides. In **aegina** *form. nov.* the upper surface is white, hindwing with narrow black border above, under surface light yellow; **marginata** *form nov.*, hindwing on both surfaces broadly margined with black, ground-colour of the hindwing beneath dark ochre-yellow. All the five forms occur in the month of January in the same locality on Palawan. — **plaetoria** *subsp. nov.* is the race from Balabac, where the species is not rare in December. ♂ beneath darker yellow than specimens from Luzon, Bazilan and Palawan. ♀: forewing white with small white subapical spots, hindwing above yellowish green with broad distal margin. Apex of the forewing and the whole of the hindwing beneath milk-white, with violet and yellowish tinge, without black distal border, but with slightly indicated submarginal band. — **minato** *Fruhst.* is the finest geographical offshoot of this species. Only the ♂ known, the forewing with the veins finely black, and with diffuse spots. Apex of the forewing and the whole hindwing beneath pale straw-yellow, the former with round black spot between the first two medians. Ishigaki, one of the most southerly Loo Choo Islands.

iria. *flaminia.* *horatia.* *aegina.* *marginata.* *plaetoria.* *minato.*

A. wardi *Moore* (60 f) replaces *paulina* in South India, and is probably a separate species. Fig. f 2 represents the rainy-season form, f 3 an intermediate form, whilst in the dry-season form the black apical margin is even more restricted, and also the distinct subapical band on the forewing beneath in the rainy form almost disappears. The ♀ closely approaches that of *paulina*, but the subapical band of its forewing is nearly twice as broad. The larva lives on Capparis heyneana Wall., South India, Nilghiris. — Finally, **yaksha** *subsp. nov.* is a very small race from the hot lowlands with pointed wings and fine, black-grey teeth to the distal part of the forewing. Under surface of both wings almost entirely white. Poona, Deesa, Bombay district.

wardi. *yaksha.*

A. nata *Kheil* (60 e), one of the most noteworthy species from the small island of Nias, above blue-grey instead of white, forewing with fine black teeth. Beneath the apex of the forewing and the hindwing have a yellowish tinge, on a grey-blue ground. Very rare.

nata.

A. cardena (60 b) is distinguished by the relatively short black hair-pencils on the penultimate abdominal tergite and the black-latticed apical part of the forewing above, which is darkest in **hagar** *Voll.* from Sumatra, whose underside, however, has in the basal area of the hindwing lighter yellow spots than **cardena** *Hew.* from North Borneo. An intermediate in the character of the pattern and colouring is **perakana** *Fruhst.* (60 b), which has the apex of the forewing somewhat more copiously decorated with white than in *hagar* and narrow, but dark orange-coloured basal margin to the hindwing beneath. Malay Peninsula.

hagar. *cardena.* *perakana.*

A. leptis *Fldr.* (60 b), a common and inconspicuous species, which occurs everywhere in Java up to 2000 ft. where remains of the virgin vegetation still exist and in many places enlivens the grassy borders of deserted coffee-plantations to the number of hundreds. Most nearly allied to the name-type is **balinus** *Fruhst.*, with essentially narrowed black subapical bands on the forewing and reduced black distal margin to the hindwing. Bali. — **vadus** *subsp. nov.* (59 d) is much larger, with more extended black bordering to both wings and very large white subapical dots on the forewing. Lombok, in May—June, very rare at this most easterly limit of its range. — **plana** *Btlr.* (59 c), described from the Malay Peninsula, and occurring in identically the same form on Sumatra, has the hindwing entirely without black distal margin, which is likewise absent in **aemilia** *subsp. nov.* from Borneo, in which also the white subapical spots of the forewing are smaller and the black subapical band is wider. — **massilia** *subsp. nov.* (59 d) is characterised by the yellowish instead of white upper surface. Palawan, common in January. — **festrada** *subsp. nov.* (59 c sixth figure) is the smallest of the known races, beneath more richly suffused with yellow than Sumatra specimens, however without assuming the almost ochre-yellow colour of *massilia* beneath. Common on Nias.

leptis. *balinus.* *vadus.* *plana.* *aemilia.* *massilia.* *festrada.*

A. maria *Semp.*, from Luzon, is a very rare species, always only occurring singly, of pure white ground-colour, almost the same in both sexes. The white ground-colour projects into the black distal margin of the hindwing in the form of a nose-shaped incision, which occurs in no other species. *maria* has the black margin of the hindwing only 2 mm. broad. — In specimens from Bohol and Bazilan, **dolorosa** *subsp. nov.* (50 f), it is widened to 3 mm.; moreover the three white subapical patches of the forewing are increased in size. — In **adorabilis** *subsp. nov.* the border of the wing is widened to 4—5 mm, so that it reaches the cell. Mindanao. In all three races there is proximally to the violet-tinged distal border of the hindwing a beautiful yellow tone, which spreads over the whole wing and shades off imperceptibly into the yellowish white basal area.

maria. *dolorosa.* *adorabilis.*

16. Genus: **Phrissura** *Btlr.*

A Philippine genus, which has extended southwards to Celebes. Only one species known, of which a number of island races still remain to be discovered. The butterflies fly slowly at the edges of woods,

rest on projecting twigs and leaves in the undergrowth and occur sporadically, but are sometimes, as for instance on Palawan, very abundant.

aegis. **Phr. aegis** *Fldr.* (62 c), described from Mindanao, has beneath a rather broad black sub-
illana. apical transverse band, which in specimens from the North Philippines, **illana** *Fldr.*, is even more strongly
caepia. developed. — In the much smaller **caepia** *subsp. nov.* (62 c) this band is partly effaced. The ♀♀ vary strongly, no two are alike, and together with the dark principal form there are specimens with almost entirely white hindwing and still more extended, almost pure white median band on the forewing, ♀-f.
nivata. **nivata** *form. nov.* (62 d). Underside of the hindwing dark straw-yellow. Palawan, common in January;
gerasa. Domoran. — **gerasa** *subsp. nov.* has a broader wing than *caepia* and an almost triangular black apical spot
polisma. on the forewing without white strigae, which projects into the cell. Sula Mangoli. — **polisma** *Hew.*, from
aegina. North Celebes; in this form the black apical border of the forewing is repeated beneath. — **aegina** *Fruhst.* (62 c), from South Celebes, is somewhat larger than *polisma*, with long thin streaks in the apical area of the forewing, which beneath is distally only slightly tinged with white-grey.

17. Genus: **Ixias** *Hbn.*

The members of this genus have the same habits of flight as *Huphina*; in neuration they differ from *Pieris* and *Appias* chiefly in the shorter and broader cell of the hindwing. But judged by the shape of the valve they would have to be placed next to *Appias*. — Head rather large and like the thorax adorned partly with bristly, partly with silky hairs. Palpi with strongly curved basal joint and very small terminal one. Antenna comparatively short with pear-shaped club. Forewing with four-branched subcostal, of which the first two veins arise before the end of the cell, the third and fourth forming a longer fork than in *Appias*. Upper radial coincident with the subcostal to about $^1/_5$, in which *Ixias* differs essentially from *Teracolus*.

Larva on Capparis; head small, segments 2, 3 and 4 the broadest, the rest narrowing posteriorly, colour uniform transparent yellowish green. Each segment from 4 to 11 bears inconspicuous reddish spots. Pupa canoe-shaped, strongly curved upwards and especially at the anterior end very pointed, of light ochre yellow colour, with a narrow, dark dorsal stripe and a fine line on each side. Pupal stage of *pyrene* 14—15 days. Larvae of all sizes were found on the same bush, which was in places eaten bare by them (Lang). — The butterflies fly rapidly in the heat of the day from flower to flower, on which the somewhat more sluggish ♀♀ live exclusively. In districts with but little vegetation the ♂♂ are fond of congregating at wet places, where they introduce a pleasing variety of colour into the large crowds of white Pierids. Most species inhabit the hot plains, and I always found them in the greatest abundance not far from the sea; some species, however, prefer mountainous districts, but appear never to ascend above 4—5000 ft. Most of the species are common, some very local, such as *venilia* and *balice* from Java, and only a few races, as *undatus* on Borneo, really rare. Almost all the *Ixias* are on the wing throughout the year and there seems to be a continuous succession of broods; all show a tendency to form climatic varieties; both sexes are moreover very variable and subject to local as well as insular variation, hence until quite recently a considerable number of mere forms were regarded as separate species.

I. pyrene is the most widely distributed, the most variable and at the same time the largest
insignis. species of the genus. — **insignis** *Btlr.* (72 b) is the most northerly race known, and is distinguished from all the allied forms by the orange-coloured subapical spot, which extends far into the cell of the forewing. The ♀♀ resemble those of *pyrene* (71 c), the cell is densely dusted with grey-black, but the white subapical band also crosses the apex of the cell, at the discocellular is placed a large isolated black patch, which is present also in the ♂♂ though much smaller, but is absent on the figure, which was taken from the type in the British Museum. Hindwing finely powdered over with grey and with very broad black distal margin, deeply dentate proximally. Not very rare at elevations of 4000 ft. in July and
hainana. August. Formosa. — I characterise as **hainana** *subsp. nov.* a form in which the orange band only covers the first third of the cell of the forewing, but is still always essentially broader than in the continental races. The subapical band is not red-orange but a peculiar ochre-yellow, much as in *salangana* (72 c).
pyrene. Hainan. — As **pyrene** *L.* we must regard the Chinese race, which Linné has named from a ♂ of the dry-season form (71 c), whilst Cramer figured the ♀♀ belonging to it as *aenippe* (71 c). The rainy-season form is much larger, all the black margins are broader and in the ♀ the white subapical band of the forewing is narrower, being sometimes nearly entirely replaced by black (71 c). The rainy-season form passes in collections under the names *rhexia F.*, *scsia F.*, *evippe Drury.* — In Yunnan occurs a specially
yunnanensis. fine and handsome race, with the base of the hindwing above suffused with red-yellow, **yunnanensis** *Fruhst.*, which is also distinguished by reddish instead of yellowish bands on the forewing of the ♀♀. — In Tonkin we meet with a further local form with especially broad black margins to the wings and
tonkiniana. relatively narrow, dark orange-coloured subapical spot in the ♂♂, = **tonkiniana** *Fruhst.* (71 c). The ♀♀ are smaller than those of *yunnanensis*, but have in common with them the reddish tinge of the subapical band

of the forewing and the upper surface of the hindwing, which in *tonkiniana*, however, is less conspicuous; but the difference in tone from the more westerly races is still always distinctly evident. The dry-season form of the Tonkin race I have called **denigrata** (71 e). — In Annam flies a smaller *pyrene*-race; in its northern provinces a yellow, in the southern districts a white-winged form, whose ♀♀ I call **annamitica** (72 a), and which form a transition from *pyrene* to *verna*. — In Siam occurs a smaller race, **verna** *Druce* (71 e), of which the ♂ of the rainy-season form with yellow upper surface (71 e, 6) and the ♀ of the dry-season form with white upperside (71 e, 5) are figured. *verna* was formerly regarded as a separate species, but the examination of the genitalia proved its complete identity with *pirenassa* from India. *verna* is one of the commonest butterflies in Central Siam, especially in January and February. There, however, I took the ♂♂ only at wet places, whilst in Annam in the previous year at the same time I captured both sexes exclusively at flowers. — In Tenasserim and Burma *pyrene* has developed again into a somewhat larger race, of which the rainy-season form has been described as **moulmeinensis** *Moore* (= meipona *Gr.-Sm.*) (72 a) and the dry-season form as **latifasciata** *Btlr.* (= pallida *Moore*, citrina *Moore*) (71 e). — On the island of Salanga occurs a race which has not yet been named, **salangana** *subsp. nov.* (72 c), with much widened and very dark subapical bands on the forewing. — In the Anterior Indian race, **pirenassa** *Wall.*, the variability of the species reaches its maximum, so that we have devoted 10 figures to this race, of which **rhexia** (71 b, 2) represents the ♂, 71 c, 2 *rhexia*-♀ the rainy-season form — 71 c, 1, 3, 4, 5 intermediate forms — 71 c, 6 and 71 d (*aenippe*) dry-season forms. *pirenassa* is distributed to Assam and Burma, where it is supplanted by *latifasciata*. Together with *pirenassa* occur in the hot lowlands of Bengal and of the Bombay district other especially extreme forms of the rainless period, which have been named *kausala Moore* (71 d), *satadra Moore, ganduca Moore, pygmaea Moore*, also *frequens Btlr., watti Btlr.*, and finally *jhoda Swinh., colaba* and *alena Swinh.* Some of these forms are apparently local, but this question cannot be settled on the continent without studying the material in the British Museum; sharp boundaries, however, can nowhere be laid down. In spite of this superfluity of names the South Indian race, which might have been named with some amount of justice, seems to have been quite ignored. It closely approaches the Ceylon race, which by modern English authors with the exception of Butler has been erroneously united with *pirenassa*; **cingalensis** *Moore* (71 d) differs from all the continental forms in the narrower orange band of the forewing in the ♂♂ and the distinctly angled subapical band in the ♀♀. *cingalensis*-♀♀ again vary considerably among themselves, besides examples with the band on the forewing slightly tinged with red (71 d, 5) there are others with light yellow band (forma **connectens** *form. nov.* 71 d) and even with entirely white upper surface and white transverse band (forma **nivescens** *form. nov.* 71 d, 72 c). — **andamana** *Moore* is another well differentiated race, which on account of its washed-out colouring was united by Bingham with *verna Druce*. Its extreme dry-season form is called **lena** *Swinh.* — From Borneo **undatus** *Btlr.* (71 b) is known, with strongly angled orange band on the forewing. The butterfly is rare, the ♀ being still altogether unknown. — **birdi** *Btlr.* is a nearly allied form from the Malay Peninsula, likewise very rare; the ♀ is also still to be discovered. Essentially smaller and beneath densely streaked with black in contrast to the altogether unmarked *undatus*.

denigrata. *annamitica.* *verna.* *moulmeinensis.* *latifasciata.* *salangana.* *pirenassa.* *rhexia.* *cingalensis.* *connectens.* *nivescens.* *andamana.* *lena.* *undatus.* *birdi.*

I. ludekingi *Vollenh.* (72 c) closely approximates in the ♂ to *andamana*, but the yellowish tinge on the submarginal area of both wings above is completely suppressed and the subapical band of the forewing is yellowish instead of dark orange-colour. The ♀ has only a very slight yellowish tinge on the band of the forewing. The ♀♀ are very rare; scarcely one is found to 100 ♂♂. The headquarters appear to be in western Sumatra; in the north-east of the island it is only found occasionally.

ludekingi.

I. malumsinum *Thieme* (72 c) is hitherto only known from Nias, but allied races may also be looked for from Siberut and the Batu Islands. The ♂ differs from the figured ♀ in the fiery red orange spot, which is extended to the base of the forewing and posteriorly reaches the submedian. Hindwing as in the ♀, only with somewhat narrower black marginal band.

malumsinum.

I. balice *Bdv.* (72 c). Noteworthy on account of the peculiar plain colouring of the exceedingly rare ♀♀, which only bear a narrow black irregular stripe at the apex of the cell, not reaching the costal. The rather broad orange spot of the ♂♂ shades off proximally into the ground-colour of the basal area, from which it is not separated by any black band. I found the ♀ only on the plateau of Pengalengan, but I have recently also seen ♂♂ from the neighbourhood of Batavia.

balice.

I. flavipennis *Gr.-Sm.* (72 b, d) is a completely isolated but not rare species, of which no near allies are yet known. The sexes are strikingly different, the ♀ entirely white, with strongly dentate black distal margin to the hindwing. The ♂♂ are fond of congregating in small clusters on the sand-banks of the mountain-streams, but the very rare ♀♀ are inhabitants of the woods. The species occurs all the year round. Sumatra.

flavipennis.

I. marianne *Cr.* (72 a). Originally described from the Coromandel Coast of South India, where it almost agrees with the specimen figured from Ceylon. — **cumballa** *Swinh.* (72 b) is the name given in collections to a handsome, extreme rainy-season form with broad black margins from Bombay and the adjoining districts, of which **agnivena** *Moore* (= depalpura *Btlr.*, meridionalis *Swinh.*) (72 b) is a dry-season

marianne. *cumballa.* *agnivena.*

form. — Finally, an especially extreme form of the rainless period, from Mahableswar in northern Bombay,
nola. has been described as **nola** *Swinh.* (72 b).

venilia. **I. venilia** *Godt.* (72 d) occurs exclusively on Java and is even there very local, being met with in numbers only in the south of the province of Kediri. The ♀♀ vary somewhat; besides the form figured, with yellow upper surface and red-orange-coloured subapical spot, there are also some which have the upper surface pure white, with a deep yellow transverse band, in which at the discocellular there are only traces of a cadmium-yellow tinge. These ♀♀ are also beneath predominantly white, with yellowish margins.

piepersi. **I. piepersi** *Snell.* is the only species of the genus which I have not before me; it is intermediate between *venilia* and *reinwardti*, but is larger than the former. *piepersi* occurs at Loka at the Peak of Bonthain and at the Waterfall of Bonthain and is even there very rare. There are 2 ♂♂ in the Berlin Museum; the species is still wanting in the British Museum.

vollenhovii. **I. vollenhovii** *Wall.* (72 d) inhabits the islands of the Timor Group and Timor itself. The ♂ figured belongs to the rainy-season form; the dry-season form is only a little inferior in size. In it the black distal margin of the hindwing is suppressed and the under surface assumes a pale white-yellow tone.

reinwardti. **I. reinwardti** *Vollenh.* (72 e) occurs on all the islands from Kangean and Bali to Timor and Alor, and is everywhere common. It forms an ornament of the coast districts in which, on Lombok, it flies in large numbers. The ♂♂ are swift fliers and visit flowers, but on specially hot days congregate at moist river-banks in small groups. The ♀♀ flutter through thorn-bushes and are fond of hiding among thorny,
kangeana. arborescent Euphorbiaceae. — **kangeana** *subsp. nov.* (72 d) differs from the more easterly races in the much smaller yellowish red discal spot, the very thick black veins of the forewing and the specially deeply dentate distal border of the hindwing. Under surface of both wings very sparsely marbled with brown.
baliensis. Kangean. — **baliensis** *Fruhst.* (= pulchrior *Btlr.*) is the form from Bali, hitherto only known in 2 ♂♂, but which may probably also occur in eastern Java. The ♂ is characterised by a very large blue-dusted basal area, a very light discal spot posteriorly bordered with intensive yellow, and by fine black transverse
lombokiana. stripes on the forewing. — **lombokiana** *subsp. nov.* (72 e) differs from the name-type (which was probably described from Timor or Flores) in the smaller dark red median spot and the large roundish submarginal patches of the forewing. The ♀ occurs in three forms: the one figured (72 e) with yellow upper surface;
noctula. an intermediate form **noctula** *form. nov.* (72 e), almost entirely black, occurring in the wet season; and a
reinwardti. variety with white upper surface, belonging to the dry period. — **reinwardti** *Vollenh.*, of which we figure the dry-season form (72 e). has the underside of the hindwing in the ♂♂ pale yellowish white. The brood of the rainy season is a little larger, more broadly striped with black; the ♂♂ beneath yellow, with strong brown submarginal spots. The ♀ recalls *noctula*, but is larger, the forewing beneath with greenish yellow cell, broad yellow-grey stripes beyond the cell, base of the hindwing dark ochre-yellow with very broad
pagenstecheri. violet-black distal margin variegated with yellow. Flores, Timor, Sumbawa, Alor. — **pagenstecheri** *Röb.* differs in the ♀, of which only the white dry-season form is known to me, in the broader black discocellular band of the forewing; Sumba.

kuehni. **I. kuehni** *Röb.* (72 d ♂, 73 a ♀) is a completely modified *reinwardti*, whose ♀ exhibits a retrogression to the *pyrene*-group in the bright orange-coloured transverse band on the forewing above. The cell of the forewing is entirely black. There are two ♀-forms, the one figured with entirely white upper surface to both wings and one with the wings light yellow above, which latter was already known to the author of the species. Wetter.

18. Genus: **Dercas** *Dbl.*

The principal characteristic of this genus consists in the short but very broad cell of the forewing, which scarcely reaches to ⅓ of the wing. The second subcostal vein arises exactly at the apex of the cell and the third and fourth veins form a large fork. Precostal vein of the hindwing relatively long, straight. Antenna short, gradually thickened. Forewing either deeply dentate or with the apex much produced. — Only a few species, of rapid flight; they are nowhere very rare, without, however, occurring in great abundance. In contrast to their nearest allies, *Gonepteryx* and *Catopsilia*, they are divided at very short distances into geographical races. All the species occur in the mountains but at medium heights and have scarcely been observed above 4000 ft.

D. verhuelli, described from China, where it occurs in Hong-kong and in the Canton district, not being very rare. I met with the species also in Tonkin, where it occurs in three forms: namely as forma
verhuelli. **verhuelli** *Hoev.*, which was figured in the Palearctic part (vol. I, 27 e). ♀-form **rufolineata** *form. nov.*
rufolineata. (67 c), in which the red longitudinal stripes are even more strongly expressed than in the principal form,
skertchlyi. but the black distal margin is much narrower; and a ♀-form which Nicéville has described as **skertchlyi** (67 c), with likewise reduced distal margin but without a trace of reddish longitudinal bands. —
doubledayi. In India proper two local races may be separated: **doubledayi** *Moore* (= menandrus *Fruhst. i. l.*) (67 d,

under the *i. l.* name *menandrus*), from Sikkim and Bhotan, whose ♀♀, as far as known to me, are always light sulphur-yellow, whilst in Assam, Manipur and Tenasserim a subspecies occurs with exclusively pure white ♀♀: this is **pallidus** *subsp. nov.* (67 d). *pallidus.*

In the Macromalayan district occurs **D. gobrias,** whose ♀♀ are analogous to the continental Indian races, being pure white in **gobrias** *Hew.* (67 e) from Borneo and Nias, whilst I have only yellow ♀♀ before *gobrias.* me of **herodorus** *subsp. nov.* (67 d), which is common in West Sumatra. *herodorus* was also once taken on *herodorus.* Java, but has apparently not been observed there for the last 20 years.

D. lycorias is the older name for the species better known as *wallichi,* which is divided into two geographical races, both showing a parallel dimorphic tendency in both sexes: **difformis** *Nicév.* (= enara *difformis.* *Swinh.*) (67 e), the larger Chinese subspecies, whose ♀♀ either bear a large black transcellular spot or are without it; and **lycorias** *Dbl.* (67 e), from Sikkim and Assam, with round discal spot on the forewing, *lycorias.* which in examples from Assam is commonly absent: forma **decipiens** *Nicév.* (= brindaba *Swinh.*) (67 e). *decipiens.*

19. Genus: **Gonepteryx** *Leach.*

This prominent Palearctic genus is only represented in the Indian Region by three species. The representative Chinese forms are dealt with in detail in the Palearctic part (I, p. 60 and 61), to which the reader is also referred for the generic description. *Gonepteryx* differs from *Dercas* in the much longer cell of the forewing and the much shorter precostal of the hindwing, which is reduced to a knob.

G. rhamni L. (vol. I, p. 60, pl. 24 c), a butterfly frequently noticed in European newspapers, appears also in continental India, where it forms a local race as **nepalensis** *Dbl.* (vol. I, p. 61, pl. 24 c), which can *nepalensis.* easily be distinguished by the deeper yellow of the ♂♂, the larger orange-coloured round patches, especially in the ♀♀, and the more robust subcostal and median veins of the hindwing beneath in both sexes. *nepalensis,* which is distributed as far as Nepal, is very common in North-West India and Kashmir and is a typical garden butterfly, favouring inhabited places up to elevations of 10,000 ft.; it has also been observed singly in Sikkim, Assam, Burma and the Shan States.

G. zaneka *Moore* (73 a) is a very distinct species with sharply dentate hindwing, the ♂♂ have the *zaneka.* forewing a beautiful sulphur-yellow and the hindwing white; the ♀♀ are white throughout. Not rare in some parts of the North-West Himalayas, but in contrast to their allies only occurring in dense woods at elevations of from 6—8000 ft. The butterflies are strong fliers and like our *rhamni* long-lived and tenacious of life,, so that they are mostly taken in worn condition. — **zanekoides** *Nicév.*, which is rarely *zanekoides.* brought to Europe, is somewhat larger, with rounder wings, and the ♂ also on the hindwing yellow towards the base. Upper Burma, found at elevations of 7000 ft. — **chitralensis** *Moore* is the most westerly form, *chitralensis.* in which the yellow on the forewing is reduced to the proximal half, whilst the hindwing shows a slight yellowish basal tinge; Chitral, in July and August, observed at between 9 and 14,000 ft.

G. amintha Blanch. (vol. I, p. 62, pl. 24 e). This magnificent species, hitherto only known from West China, has been recently discovered also in Formosa, where it has developed a race, **formosana** *Fruhst.*, *formosana.* with the forewing still darker and deeper orange-yellow, and the red discal patches on the hindwing almost twice as large as in continental specimens. The species appears to be very local on Formosa, as I have hitherto only received 6 ♂♂, all taken in April in Taihanroku near the southern point of the island.

20. Genus: **Catopsilia** *Hbn.*

The species of this widely distributed genus, without being particularly numerous, play a prominent part in the landscapes of four continents. They follow man everywhere, and appear so much the more abundantly the more energetically the primeval woods of the tropics are cleared for cultivation. Nearly all the species occur all the year round, the broods appearing to follow one another continuously. The larvae consequently occur in enormous numbers, sometimes destroying valuable plantations in the course of a few days and being thus only a little less injurious than the dreaded scourge of locusts. The butterflies commonly fill the air like snowflakes, crowding out other species from the districts attacked by them. More than any other Pierids they follow the migratory tendency already mentioned in the introduction to this family. 75% of the flights consist of ♂♂, but the ♀♀ often lay their eggs during migration, so that their food-plants are so covered with them that it looks as if handfuls of sago had been scattered over them. The migratory swarms prefer the sea-shore or broad roads leading through the forest, according to Dr. Manders simply to avoid obstacles. The original cause of these migrations may have been the necessity of searching out new food supplies for their offspring. — Both sexes are fond of feeding at flowers, but are equally partial to wet places in gardens or roads or on river-banks. They possess the

most fully developed scent-apparatus of all the Pierids. In neuration they approximate most nearly to *Dercas*, but the cells are longer, the fourth subcostal vein shorter and the second arises at the end of the cell. Precostal reduced to a thick knob.

Egg very pointed on both poles, mostly yellowish white. — Larva cylindrical, green with a pale lateral stripe and shagreened upper surface; on species of Cassia. Pupa canoe-shaped.

Most species are very variable; on the continent all race-characteristics are obliterated by the migrations, but on the eastern groups of islands local forms have been developed. Some species are armed like *Prioneris* with costal teeth; a character which, however, is not so constant as in the Neotropical species, since in *catilla* and *crocale* for instance examples occur with and without such armature. Uncus moderately small, narrow, but long rostrum-shaped, valve distally not rounded and uniform, but deeply incised, bipartite, furnished with long bristles.

pyranthe. **C. pyranthe** *L.* is above white, with black distal margin to the forewing, the intensity of which varies according to the time of year. In the dry-season form it is scarcely indicated, in the rainy-season form strongly widened (♂ = cluryseis *L.* [69 e], ♀ = alcyone *Cr.* [69 e, 2 and 3]). The dry-season form (gnoma *F.* [69 e] = philippina *Cr.* [69 e, 1 and 2]) may also be recognised by the fact that on the underside of both wings there are large silver discal spots and a confusion of reddish dots, much as in *florella F.*

The species is widely distributed, from Formosa, Hong-Kong and the Philippines through the whole of South Asia to Ceylon and Macromalayana.

Egg shiny white. Larva dark green, laterally with yellowish white stripes, which are bounded above by black-dotted lines. The dorsum and the head densely spotted with black. On species of Cassia. Pupa green with the angles marked with yellow. Pupal stage lasts 7 days. SEMPER mentions the interesting fact that the duration of the pupal stage lasts a longer or shorter time according to the season. It continues in April and May six or seven days, in September eight and in December nine. SEMPER explains this on the ground that the life-cycle of the individual is completed in a shorter time in pro-
evangelina. portion as the climate becomes more uniformly warm and moist. — **evangelina** *Btlr.* (69 e), characterised by the rounder shape of the wings and the smaller black dots at the apex of the cell of the forewing, is the geographical form from Micromalayana, originally described from Flores, but also occurring in Sumbawa
lactea. and westwards as far as Bali. — **lactea** *Btlr.* is a race from Australia and the Solomon Islands, which is unknown to me in nature.

florella. **C. florella** *F.* (69 d) differs from *pyranthe* in having the distal border of the forewing always broken up into separate black spots, the antenna red instead of black, the forewing also tinged with yellow and the under surface always yellow instead of greenish white and copiously marbled with red in both seasonal forms. The rainy-season form (on 69 d designated by error as *philippina*) differs in the larger size and the more extended black markings on the upperside, whilst the markings on the under surface do not differ. — Larva pea-green, with distinct orange-coloured lateral stripe, lightly sprinkled with black; horn on the head reddish brown. In Asia distributed from China over the whole of India to Ceylon, then over Persia to Aden and indigenous in the tropical districts of Africa. For its occurrence in the Palearctic Region see vol. I, p. 59.

crocale. **C. crocale** may perhaps be called the commonest butterfly of the East Indies, and forms together with the following species those enormous periodical flights of butterflies whose individuals number hundreds of thousands. But even when not thus congregating, they predominate in the plains wherever there is open country covered with vegetation, fluttering restlessly from flower to flower or settling in enormous numbers on the banks of rivers, so that they sometimes even startle the horses of passing travellers when they suddenly fly up in alarm with a buzzing noise and disappear in all directions, only to return again to the drinking places after a short time, when the danger is over. The species is widely distributed, from southern China over the whole of South Asia and from Ceylon to the Solomons, where, however, it becomes rare. — Egg yellowish white, pointed at both ends. Larva on species of Cassia, when just hatched light green, full grown deep grass-green, darkest dorsally with a cream-yellow lateral stripe. Pupa green, sharply angled, with yellow lines and black tubercles. — The imagines are very variable,
flavescens. the ♂♂ appear in two principal forms, namely with the upper surface entirely yellow (**flavescens** *form. nov.*)
alcmene. (69 c) or with yellow basal but white distal half to both wings (**alcmene** *Cr.* ♂ 69 c). The width of the black distal border of the forewing appears to vary according to the time of year. The under surface of both wings is without eye-spots, the antennae in both sexes black. The large majority of the ♂♂, like those of *Prioneris*, bear at the costal margin of the forewing strong, chitinous, red-brown teeth, distinctly perceptible with the finger, obliquely placed, laterally again provided with points, which are perhaps only modified scales. Out of 45 ♂♂ examined in the collection FRUHSTORFER 21 bear these probably secondary
jugurtha. formations. — In the Indian faunistic region and in Macromalayana occur only 2 ♀♀-forms, namely **jugurtha** *Cr.* (69 c), with predominantly white upper surface and slight yellowish basal tinge on the hindwing,

indistinct black submarginal bands and whitish under surface; and **crocale** *Cr.*, which varies from pale to dark yellow, changing into ochreous especially often in examples from Macromalayana, and has sharply marked black submarginal bands and dark or reddish yellow under surface. — ♀-f. **latilimbata** *form. nov.* (69 c, second figure, as *crocale*) is the predominant form on Java, which bears also beneath black or brown-violet bands on a white ground with mother-of-pearl gloss. Specimens from Anterior India are never so intensely black as the specimen figured and mostly much larger. — **micromalayana** *subsp. nov.* is the name given here to the form from the lesser Sunda Islands, which is distinguished by the uniform yellow tint of the upper surface of both wings in ♂ and ♀. In it occurs for the first time on the way towards the east a ♀-form similar to the ♂, without a trace of black subapical spots on the forewing; this is ♀-form **virosa** *form. nov.* (68 e). Among the ♂♂ the half white, half yellow aberration (= *alcmene Cr.*) is very rare. True ♀-f. *virosa* is known from Sumba and Alor, but a similar form also occurs in Celebes and in New Guinea. — **celebica** *subsp. nov.* (68 e, 69 a), as is nearly always the case in Celebes butterflies, is the largest of the *crocale*-races, and is further characterised by the occurrence of an almost entirely black ♀-form, **ostentata** *form. nov.* (69 a), which, however, is connected by all transitions with the lighter ♀♀-forms and even with ab. *virosa Fruhst.* Celebes, Saleyer, Kalao. — **flava** *Btlr.* (68 d, e) approaches *celebica*, but is mostly somewhat inferior in size; also no darker specimens are known than 68 d 4, a ♀-form for which the name **rivalis** may be introduced; whilst 68 d 5 may be designated as ♀-form **crocalina** and 68 e 2 as **jugurthina.** Moluccas, New Guinea, Australia, Bismarck Archipelago, Solomons.

crocale. *latilimbata.* *micromalayana.* *virosa.* *celebica.* *ostentata.* *flava.* *rivalis.* *crocalina.* *jugurthina.*

C. pomona *F.* (69 b) differs from the preceding species in the red instead of black antennae, the occurrence of white silver dots in the disc of the underside of both wings, the lesser variability of colour in the ♀♀, greater rarity, and according to Martin and the Anglo-Indian collectors in the fact that it always keeps to the woods and is never found in open country. Also the sexual organs of *crocale* and *pomona* are different; in the former the distal parts of the valve are roundish, almost equally broad, and the penis is non-dentate ventrally; in *pomona* the upper valvular process is very small, pointed, and like the larger wings acutely angled, and the penis is distinctly dentate ventrally. But in opposition to these morphological differences is the fact that both de Nicéville and Hagen state that the two species have been bred from the same brood of larvae. Moore regards *pomona* as a pale seasonal form of *catilla*, which I cannot endorse, as all the forms fly at the same time on Java. The question therefore still remains to be settled, and for the sake of simplicity we follow here the majority of entomologists and treat *pomona* as a separate species. Of the ♂♂ before us from Java 33% belong to the form **aserrata** without serrations of the costal margin of the forewing, whilst 20 out of 30 specimens of the form **serrata** are armed with such costal-marginal points. The ♂♂ vary still further, like those of *crocale*, most of them belonging to the form **hilaria** *Cr.* (69 c), with yellow base and white distal part on the upper surface of the wings; the ♂♂ with entirely yellow upperside might be called **citronella.** They are the predominant form on the lesser Sunda Islands. For the ♀-form named *pomona* on 69 b, with the surface of the wings white on both sides, we introduce the name **nivescens;** beautiful dark yellow ♀♀ with broadly diffuse blood-red spot on the under surface of the forewing are **catilla** *Cr.*; this aberration occurs also, but much more rarely, on a white instead of yellow ground; this is **siscia** *form. nov.* A further noteworthy aberration consists of those specimens in which the hindwing bears beneath only 2 large round patches at the subcostal veins (= **bidotata** *form. nov.*), which do not form a continuous spot as in *catilla*. It occurs especially in Micromalayana. The local differences are not so pronounced in *pomona* as in *crocale*, and only the Celebes form deserves further mention as **perspicua** *form. nov.* (69 b). Here both sexes are considerably larger than the other Malayan examples; ♀ distinguished by the black-brown submarginal band being complete and traversing also the hindwing. ♂ above only a little lighter distally than the ♂♂ of *crocale celebica Fruhst.* — **hinda** *Btlr.* is the Australian race, above a peculiar cream-colour, beneath a magnificent ochre-yellow; from Queensland.

pomona. *aserrata.* *serrata.* *hilaria.* *citronella.* *nivescens.* *catilla.* *siscia.* *bidotata.* *perspicua.* *hinda.*

C. scylla is a purely Malayan butterfly, which has spread northwards from Macromalayana to Tenasserim and Siam, and towards the east has reached the Moluccas. The ♂♂, with the exception of insular differences, are very constant; in the ♀♀ the influence of the seasons is noticeable in the occurrence in the Micromalayan region of distinctly paler dry-season forms (♀-f. **ascylla** *Fruhst.* [68 a]) and on Celebes of a wholly darkened ♀ in the rainy season (♀-f. **minacia** *form. nov.* [68 b]). The name-type **scylla** *L.* (68 a) comes from Java, where the species is not rare up to elevations of 2000 ft. and occurs everywhere in gardens and open country. It is also found on Bawean, Bali and Lombok. — In Sumatra, the Malay Peninsula and Siam occurs a race which has somewhat less black (68 a, fig. 3 and 4 from Sumatra). — **sidra** *subsp. nov.* (68 b ♂; 68 c ♀, on the plate as *scylloides*) is the larger and darker race from Sumbawa. — **scylloides** *Fruhst.* (68 b ♂, 68 c 2 ♀), originally described from Babber, which also inhabits Tenimber, Wetter and other islands east of Timor, is a smaller geographical race, with paler colouring in the ♀. — **asaema** *Stgr.* (68 b), the largest of the known forms, is distributed over the whole of Celebes, and like *crocale celebica Fruhst.* tends to form melanotic aberrations (♀-f. **minacia** *form. nov.* [68 b]). — **bangkeiana** *Fruhst.* has the black distal margin even more extended than in *asaema*, with still more distinctly marked sub-

ascylla. *minacia.* *scylla.* *sidra.* *scylloides.* *asaema.* *minacia.* *bangkeiana.*

moluccarum. marginal bands on both wings; Bangkei. — **moluccarum** *subsp. nov.* (68 c) is inferior in size to *asaema*; also the black submarginal marking on the hindwing beneath is reduced; Northern and Southern Moluccas.
etesia. — **etesia** *Hew.* is a small form (apparently even smaller than *scylloides*) from Australia, with the upper
praerubida. surface of the hindwing tinged with yellow; only known to us from Hewitson's figure. — **praerubida** *subsp. nov.* has in the ♀ above washed out black spots and beneath strikingly large light carmine-red submarginal patches and extended distal tinge of the same colour on both wings. Flores. — The larva according to Martin is velvety green, with a yellowish white lateral stripe and some very small black spots, the whole upperside finely ringed and incised, as in a leech. Pupa with pointed head, similar to that of *crocale*, but shorter and more convex than the slender pupa of the latter. — A further race, which we have not seen in nature, is known from Luzon in two specimens only.

gorgophone. **C. gorgophone** *Bdv.* (68 d), distributed from Cape York to Sydney, is apparently rarely brought to Europe; the ♂ differs from the figured ♀ in the absence of the black submarginal spots of the forewing. The under surface is as in *scylla*.

21. Genus: **Colias** *F.*

Of this important Palearctic genus we have here only a few species to deal with, which are frequently only offshoots of Transhimalayan species and differ but little in their southern localities.

Like *Parnassius*, *Colias* forms one of the most homogenous genera of all the Lepidoptera; they are certainly among the oldest extant and their origin can be traced back to the middle of the tertiary age. The similarity of some species to *Pieris callidice* suggests a direct development from that genus. But in spite of all the superficial resemblance of the species one to another, the pattern and colouring are extraordinarily inconstant, and most species are inclined to .local variation, also hybridisation seems to occur rather commonly (an exceptional thing among the butterflies). It has been proved that the membranous scales, that is those which are placed on the larger interneural areas, may be employed as a pretty reliable character for differentiation. The marginal scales (fringes) are with a few exceptions light red or rose-coloured. Besides the vein-scales there are often also highly specialised scent-scales, which in the ♂ are placed at the base of the hindwing. But as the ♂ pursues the ♀ for copulation they can scarcely be of value for purposes of attraction. and we are therefore inclined to regard them as stimulating organs.

Colias differs from *Catopsilia* in the second subcostal vein arising beyond the cell and in the still less developed precostal; on the forelegs the claws are entirely without the appendages (paronychia) which are present in all the other Pierids.

C. hyale (see vol. I, p. 65. pl. 25 g), one of the commonest European butterflies, inhabits those districts of North-West India which belong to the Palearctic zone, from whence it has extended to Bhotan in
poliographus. the east and the Nilghiris in the south. **poliographus** *Motsch.* (= simoda *Orza*) (I, p. 65, pl. 26 a) is the principal form of Japan, which reaches the tropical region on Ishigaki and Formosa and is also occasionally taken as an immigrant on Luzon. In Japan and on Tsushima *poliographus* is one of the predominant butterflies, the first messenger of spring, which already begins to appear when the snow is still lying, and that not in hibernated specimens but freshly emerged from the pupa. On Tsushima I met with *hyale* as late as the middle of October — a handsome form, mostly with white ♀♀ — where it still enlivened all the meadows in hundreds. — From the extreme north of Japan a form deserves mention which has very
napata. fine, dot-like yellow subapical spots on the forewing, usually of very small size (f. **napata** *form. nov.*). Similar examples to those figured by Leech pl. 24, fig. 14 seem to occur occasionally, as I brought one
murina. with mouse-grey instead of black apical tinge on the forewing from Nagasaki (f. **murina** *form. nov.*). In Kioutchou flies a relatively small dark race, which approaches *crate* in the broad black apical tinge of the forewing. — In the high mountains of West China appears to occur exclusively a gigantic form with
pyxagathus. particularly bright light lemon-yellow colouring (**pyxagathus** *form. nov.*). — Specimens with gold-yellow tinge on the forewing in the Fruhstorfer collection from Japan recall the variety *radiiformis Schultz*,
glicia. known from Europe. — **glicia** *subsp. nov.* (72 f) is the not rare and apparently constant form occurring in Kashmir, which is conspicuous by the continuous, relatively large yellow subapical spots on the forewing
lativitta. and recalls *sareptensis Stgr.* from South Russia. Known from elevations of 14—15,000 ft. — In **lativitta** *Moore* (72 f), from North-West India, these small yellow spots are absent, in which this form approaches
nilagiriensis. *crate*. — **nilagiriensis** *Fldr.* (72 f) is a very small race with very broad black distal margin, particularly in the ♀, which on the forewing has scarcely any trace of whitish dusting. Nilghiri Hills, South India, known from elevations of 5000 ft. — As belonging to the Palearctic fauna, but allied to the Japanese
palidis. forms, we mention here *hyale* **palidis** *subsp. nov.*, from the Vilui district, characterised by a light cream-coloured upper surface in the ♂♂ and pale yellowish white, very small ♀♀. The distal border of both wings shows a tendency to fade into light grey, likewise the discal spot of the hindwing is paler. Also
naukratis. the under surface of the wings has very fine black markings. — As **naukratis** *subsp. nov.* we introduce a further form, approximating to Staudinger's *alta*, of delicate yellow ground-colour, which in size is

intermediate between Central European ♂♂ and those from Japan, with very extended yellow subapical patches on the forewing. Habitat Siberia.

As *C. aias Fruhst.* (73 a) is figured the single island race of the Palearctic *palaeno L.*, which has already been discussed in the first volume, p. 63. It differs from all the known forms in the broadened distal border of the forewing. The ♀ is pure white, with the distal border of the forewing twice as broad as in European specimens. Main island of Japan. [1])

C. ladakensis Fldr. (= shipkee *Moore*) is above brilliant sulphur-yellow, the black distal margin ornamented with large oval yellow spots, hindwing densely dusted over with black, likewise yellow-spotted. Known from Ladak and Kashmir, to which it occasionally wanders from Tibet.

C. berylla Fawcett (= nina *Fawcett*) (I, 26 c, p. 66), from southern Tibet, is a light yellow local race of the preceding.

C. thrasibulus *nom. nov.* for the name *elwesi Röb.*, preoccupied since 1881, a rare local form of *cocandica Ersch.* from Central Asia, figured on pl. 72 c as *leechi Elwes*, known from Ladak from altitudes of 15—17,000 ft. *thrasibulus.*

C. alpherakii Stgr. (I, p. 64, pl. 25 e, f) passes over the Indian boundary at Chitral.

C. dubia *Fawc.* (I, p. 67) is a species allied to the northern *sulitelma Aur.*, which was taken in southern Tibet at about 10,000 ft. and is also reported from Native Sikkim. *dubia.*

C. wiskotti Stgr. (I, p. 70, 27 d) has likewise been observed in Chitral at the Kandur Pass at an elevation of 11,000 ft.

C. eogenê Fldr. (I, p. 67, 26 c), a magnificent species, with a strong tendency to the formation of local races, is also known from the Indian empire, where it occurs in Kashmir, Ladak and Chitral — always at elevations of over 9000 ft. Of the ♀ specimens have been discovered in India with yellowish and in Baltistan with whitish upper surface.

C. miranda *Fruhst.* (72 f) was recently discovered in South Tibet, near the border of Sikkim, and is a small species varying somewhat in colour from ochre- to red-yellow; it was originally described as a local race of *eogene*. The ♀ (30, f. 5) is light ochre-yellow with broad, black submarginal band on the forewing, pale yellow distal border to both wings and a yellow oblong spot on the otherwise blackish hindwing. Kamba-Jong, from 15—17,000 ft. *miranda.*

C. stoliczkana *Moore* (72 f) is a species described from Changla in Ladak, of light ochre-yellow ground-colouring, whose ♀ approximates to *miranda*, but apart from the lighter upper surface it has also a cell-streak traversing the hindwing to the base. The ♂♂ bear moreover a black terminal margin on the hindwing which extends to the hindmargin. Flies likewise at elevations of from 4—5000 m. *stoliczkana.*

C. fieldi *Mén.* (I, p. 68, pl. 26 g) is divided into two races. *fieldi* from China is essentially larger than **edusina** *Btlr.* from India, where it is distributed from Kashmir to Bhotan and Assam. The ♀ occurs in two forms, a dark rainy-season form without yellow, and in the smaller dry-season form with yellow spots at the costal margin of the forewing. The species extends from 5—12,000 ft. and is in many places very common. BINGHAM has recently discovered it also in Upper Burma. *fieldi.* *edusina.*

22. Genus: **Terias** *Swains.* [2])

The species of this almost cosmopolitan genus come in such abundance in consignments from the tropics that together with *Catopsilia* and certain Danaids they are a bugbear to the collector, but very unjustly, for they deserve perhaps more than other more attractive butterflies an exact study, which on account of the tendency of the species to develop horodimorphic, local and insular forms is as difficult as it is interesting. Although in general very variable, some apparently insignificant characters remain strikingly constant, such as the occurrence of only one, two or three black dots in the cell on the underside of the forewing. The subapical marking of the forewing beneath is repeated in diverse species in the most deceptive manner (*hecabe, sari*). — In neuration they approach *Colias* in the rudimentary precostal and the short and broad cell of the hindwing, but differ in two subcostal veins arising before the end of the cell of the forewing, in this cell being broader, and above all in the weak and delicate wings.

The flight of the species varies greatly; they mostly only move slowly and without energy, fluttering from flower to flower, and everywhere in the tropics enliven open places, gardens, the edges of

[1]) *C. phila Fruhst.* (73 a) was sent to me from Kashmir, but it has just been proved that the collector had by oversight mixed a faintly coloured European specimen, which he had obtained in exchange, among genuine Kashmir butterflies. Hence the name sinks as a synonym of *phicomone Esper.*

[2]) *Terias* 1820—21 is about 6 years older than the better known name *Eurema Hbn.* of 1826.

woods and open woods. Only *harina* prefers more shady forest-paths and *libythea* whirls along rapidly in the dry season. But all the species are attracted by wet places, they also congregate in swarms and their larvae are injurious to Cassia plantations.

a. ♂ without sexual spot on the forewing.

libythea. **T. libythea** *F.* may easily be distinguished from all other species of *Terias* by the extended black costal margin of the forewing and the proximally uniformly dentate and almost equally broad distal *rubella.* border of both wings. The dry-season form **rubella** *Wall.* has on the hindwing an essentially narrower distal border, which is commonly broken up into separate spots and bordered by a brilliant rose-red *senna.* terminal margin, recalling the fringes of *Colias*. The whole of India, Ceylon and Burma. — **senna** *Fldr.* is an unimportant local form from the Malay Peninsula, described from specimens of the rainy season. — *fruhstorferi.* **fruhstorferi** *Moore* (73 d), from Further India, differs from Anterior Indian specimens in the somewhat narrower distal border and more copious grey-black dusting on the upper surface of the wings. In Assam the butterflies ascend to 5000 ft., and keep by preference to dry, grassy places, shaded by pines. — *drona.* **drona** *Horsf.* is based on examples of the rainy season and might best be employed as the name of the Javan-Sumatran local form, which somewhat surpasses the Indian specimens in size. I met with it also on Lombok, at elevations of 4000 ft., where it especially frequented the wet banks of brooks. On Java and Lombok there is futher a dry-season form, smaller than that of the wet season, with very fine black, *herlina.* uniform, marginal line on the hindwing and finely undulate brown or black transverse bands on the hind- *zoraide.* wing beneath (**herlina** *form. nov.*). — **zoraide** *Fldr.* (= australis *Wall.*) belongs to the rainy-season form of *sinta.* the Australian local race, whilst **sinta** *Wall.* and **immaculata** *Misk.* denote the dry-season form. *immaculata.*

b. Under surface of the forewing with an androconial spot at the median.

venata. **T. venata** *Moore*, a comparatively rare species, very similar to *drona* and *libythea*, but with more pointed forewing and linear distal border to the hindwing. The dry-season form differs but little and has *pallitana.* narrower black margins = **pallitana** *Moore.* Kashmir, West and Central India. — In Northern India and *rama.* Ceylon occur specimens with more copious black powdering on the upper surface of the wings = **rama** *sikkimica.* *Moore.* — **sikkimica** *Moore* is the name of the somewhat more darkly margined ♂♂ from Sikkim and Bhotan, where the form occurs at elevations of 6—9000 ft.

laeta. **T. laeta** *Bdv.* (73 d) likewise has an extensive range and has the same habits as *libythea*, in whose company it is mostly found. The forewing is distinguished by its sharply produced apex, and the angled hindwing makes this one of the most easily identified species of *Terias*. The rainy-season form is beneath *pseudolaeta.* plain yellow powdered over with black. As **pseudolaeta** *Moore* is known a dry form from Tenasserim with reddish tinge and sand-grey dusting. The species is distributed over the whole of India, very common *annamitica.* in Kashmir, extending southwards to the Nilghiri Hills and eastwards to Annam and Tonkin. — **anna-** *semperi.* **mitica** *Moore nom. nud.* is probably an untenable name. — **semperi** *Moore*, erected from SEMPER's figures designates a relatively small race from the Philippines, which came from the Benguet Mountains in Luzon, whilst ♂♂ in FRUHSTORFER's collection from the neighbourhood of Manila agree more with Assam *vagans.* examples. — **vagans** *Wall.* is the Formosa race with strikingly light yellow ♀♀. — **hainana** *Moore*, a form *hainana.* from Hainan, is unknown to us in nature. — **bethesda** *Jans.*, already dealt with in the Palearctic part *bethesda.* (p. 58), is the summer form, and **subfervens** *Btlr.* the winter form of the Japanese subspecies, which *subfervens.* passes in cellections as *jaegeri Mén.* and also occurs on Tsushima and in Corea. — **herla** *Mc Leay* (= *herla.* lineata *Misk.*), which appears to be very rare, replaces *laeta* in Australia, Queensland.

sana. **T. sana** *Btlr.*, according to a figure which was drawn at the British Museum, appears to be a *venata*-race, with no marking except a distal margin, which is broader on the forewing and narrower on the hindwing. Very small.

smilax. **T. smilax** *Don.* is according to WATERHOUSE the smallest South and East Australian *Terias*, which is unknown to us in nature, very variable, so that the names *casta Luc.* and *ingana Wall.* have been introduced for the rainy-season form, *varius Misk.* for an intermediate form and *parvula Hew.* for that of the dry season. According to the figure of *ingana Wall.* the species, which BUTLER places in a separate group, appears to form a transition to *hecabe L.*

c. ♂ with two stripes of short, thick scales at both sides of the median of the forewing beneath.

The best known species of this group is **T. hecabe** *L.*, which of all the butterflies has probably received the most names, so that their correct differentiation is one of the most difficult problems of oriental entomology. The species is divided in many of its localities into 3 seasonal forms, which are connected by transitions. The most extreme of these forms can be artificially produced at the same time

by breeding, if some of the pupae are kept in a cold and others in a warm place, an experiment which PRYER has carried out in Japan. The examples of the dry season are beneath mostly ornamented with red spots, of which one sometimes covers the entire apex of the forewing beneath (f. **sodalis** *Moore*), and such specimens may easily be confused with *sari*. The ♀♀ are always larger than the ♂♂, paler, but more or less densely sprinkled over with black dots. Dwarfed and giant forms occur in the species as commonly as miscoloured ones. The eggs are laid singly, but sometimes also a larger number are deposited on a leaf in rhomboidal form. In the latter case the larva likewise lives gregariously and even the pupae are fastened near to one another in large numbers. Larva green, lightly haired, with large black head and yellowish white lateral streak. When the pupae hang from leaves, they are green, when near the flowers of Cassia, yellow, and when the larvae leave the food-plants and spin up on high grasses, they become black-brown like the seeds in their vicinity. The pupae are in this case arranged in rows at regular intervals, which completes the illusion. The butterflies leave the pupal shell after only 6 days (MARTIN). — *anemone*, already mentioned in the Palearctic part (p. 59) as a synonym, is the form which has advanced furthest towards the north. Two races are known to us: **anemone** *Fldr.*, described from Ningpo and probably distributed over the whole of Central and Northern China to Corea; *mandarina Orza*, from Japan, whose name-type is based on the remarkably poorly coloured dry-season form, whilst the rainy-season form has been named *marriesi Btlr.*, and *hybrida* and *connexiva Btlr.* refer to intermediate forms. On Tsushima I took all the forms together in October. On Okinawa there is a local race in which a summer brood occurs with large, obliquely placed red subapical spot on the hindwing beneath, which according to FRITZE has not yet been observed in Northern Japan, but of which I have seen a less pronounced form from Nagasaki and Tsushima. On Ishigaki, the most southern Loo Choo Island, occurs a *hecabe*-race which can scarcely be distinguished from specimens from Formosa and South China. — **hecabe** *L.* (73 f), the name-type of which perhaps came from China, is here dealt with as being distributed from Southern China to Anterior India. Nearly 25 names have been given to the many forms which inhabit the Indian empire alone. BINGHAM has recently lumped them nearly all together, but a number of them appear to deserve recording, as the ensemble of specimens always shows a local character, though the differences are so subtle as to be more easily comprehended with the eye than described with the pen. Thus I would retain for the products of the hot, almost rainless lowlands of India the name **fimbriata** *Wall.*, to which belong *pulla Moore*, *excavata* as rainy-season form and *narcissus*, *asphodelus* and *irregularis Btlr.* as intermediate forms, whilst *aesiopaeoides* and *swinhoei Moore* denote races of Central and Western

sodalis.

anemone.

hecabe.

fimbriata.

India, and **merguiana** *Moore* is based upon relatively large specimens from the Mergui Archipelago with deeply emarginate distal border to the forewing, of which *fraterna* and *patruelis Moore* constitute the dry-season form. — **simulata** *Moore* designates the dark yellow Ceylon race, — **nicobariensis** *Fldr.* the subspecies from the Nicobars. — **blairiana** and **andamana** *Moore* the race of the Andamans which has but few markings. — **grandis** *Moore* is founded upon specially conspicuous examples from the mountain region of Sikkim. — **simplex** *Btlr.* is based on ♂♂ with strongly reduced black, uniform distal margin — and **apicalis** *Moore* upon the most extreme form, with only a black apical spot, and as **sarinoides** *form. nov.* is here described the dry-season form with the large red apical spot on the forewing beneath, similar to that of *sari Horsf.* — **subdecorata** *Moore* designates a local race from Hainan — of which **attenuata** *Moore* is a dry-season form. — **hobsoni** *Btlr.* is the form from Formosa, which appears to differ from Tonkin and Hong-Kong examples in the more uniformly pale colouring of the ♀♀ and the darker yellow ♂♂ and also occurs on the southern Loo Choo Islands, such as Ishigaki. — On the Philippines there is a very great difference between the insects from the northern and southern islands. The race from Luzon is **luzoniensis** *L.*, small, of dark yellow colour, closely allied to the Hong-Kong specimens; ♀ plain pale yellow, without black dusting and hence very similar to *hobsoni*. — **sintica** *subsp. nov.* inhabits Mindoro. Forewing with large black spot at the apex of the cell, black-brown distal border of the hindwing relatively narrow. The whole upper surface of the wings lightly powdered over with black. — **tamiathis** *subsp. nov.* (= diversa *auct.* nec *Wall.*) is the most southerly and the darkest geographical subspecies, with very broad distal margin; upper surface of the wings densely scaled with black, apex of the cell adorned with a small, indistinct black spot. Mindanao, Bazilan, Jolo. — **jalendra** *subsp. nov.* surpasses even *tamiathis* in size; the black powdering of the ♀♀ is absent, the distal border becomes somewhat narrower in both sexes. Palawan, Balabac. — **borneensis** *subsp. nov.* (73 e) has especially in the ♀ a strongly marked distal border. North and South Borneo. — **locana** *subsp. nov.* is characterised by having the marginal bands scarcely a third as broad; Natuna Islands. — **latilimbata** *Btlr.* is the oldest name for the specially large race from Sumatra, which differs in both sexes from *borneensis* by the narrower margins. **bidens** *Btlr.* is based on a dark ♀ of the rainy-season form and *semifusca Btlr.* on a ♀ with half black, half yellowish upper surface to both wings. **toba** *Nicév.* is a small mountain form, pale whitish yellow in the ♀. North, East and West Sumatra. — **satellitica** *subsp. nov.* is a new name for the small Nias form, whose ♀♀ are powdered over with black like those of *tamiathis*. — As **sankapura** *subsp. nov.* are included the whole of the insular forms which inhabit Bawean, Java, Bali and Lombok, recognisable by the narrow black distal border, whose edge is pretty even on the forewing. — **enganica** *subsp. nov.* has on the contrary very deeply

chemys. incised marginal bands on both wings. Island of Engano. — **chemys** *subsp. nov.* is the race from Alor and Sumba, in which the ♂♂ are deep yellow and the ♀♀ have the basal area powdered over with dull grey.
brevicostalis. — **brevicostalis** *Btlr.*, a smaller form from the islands of the Timor Group, with the distal bands deeply incised proximally; Timor, Wetter, Babber, Dammer, Kisser and Key. — On Sumba occurs a similar,
dendera. kalidupa. somewhat modified race, scarcely dentate proximally: **dendera** *subsp. nov.* — As **kalidupa** *subsp. nov.* is here introduced one of the most sharply characterised island forms, whose ♂♂ recall *brevicostalis*, but are deeper yellow and bear a narrow black distal border. The ♀ is, however, densely powdered over with black throughout and the veins broadly covered with black. Kalidupa, discovered by H. Kühn. —
dentyris. **dentyris** *subsp. nov.* is a small form, with very narrow marginal band, the ♂♂ deep dark yellow but the ♀♀
asanga. without dusting on the upper surface; Tanah-Djampea, Saleyer. — **asanga** *subsp. nov.* is the race from the Northern Moluccas, which Butler unites with his *brevicostalis* from Micromalayana, to which it approxim-
sinda. ates very nearly, but differs in the more greenish yellow ♀♀. Halmaheira, Batjan. — **sinda** *subsp. nov.* is a mountain form from South Celebes, with relatively narrow black distal border to the hindwing of the ♂♂ and very large, strikingly pale yellow ♀♀. Under surface with very large red-brown apical spot; hindwing with four diffuse patches. The ♀♀ differ from the ♀♀ of *latimargo Hopffr.*, which occur with them, in the absence of black dusting on the upperside of both wings and the much reduced marginal
oeta. band on the hindwing. Peak of Bonthain, February, 5000 ft. — As **oeta** *subsp. nov.* are united all the *hecabe* occurring in New Guinea; they differ from *sulphurata Btlr.* in the darker yellow ground-colour, the
kerawara. narrow black distal margin of both wings and the deeper colouring of the under surface. — **kerawara** *Ribbe* is the name of specimens from the Bismarck Archipelago, with green-white upper surface in the ♀♀
magna. and only slightly yellow tinge on the hindwing; New Pomerania. — **magna** *Ribbe* is a similarly coloured
nivaria. race, but of larger size. Mioko. — **nivaria** *subsp. nov.*, from the Solomons, has almost entirely white ♀♀, which recall those of *biformis*, but only show traces of a yellow tinge, while the hindwing is scarcely
sulphurata. perceptibly margined with black. — Under **sulphurata** *Btlr.* its author has recently grouped together all the Australian specimens and quite a number of island races, such as *hebridina*, *aprica* (Tonga-tabu), *maroensis*, *laratensis Btlr.*, a course which will need to be tested. The Australian race is in general, in
diversa. spite of the occurrence of seasonal forms, less variable than Indian *hecabe*. — **diversa** *Wall.* is a very interesting subspecies with white instead of yellow ♀♀. The type comes from Buru; recently examples
biformis. have also been discovered on Obi. — **biformis** *Btlr.* (73 c) is the name for the little larger and somewhat
bandana. more broadly black-margined race from Amboina and Ceram. — **bandana** *subsp. nov.* has in the ♂ the same marginal pattern as *biformis*, but a light yellow ♀ with very weak black distal border.

tecmessa. **T. tecmessa** *Nicév.*, described from Penang and North-East Sumatra, in Fruhstorfer's collection from Perak and West Sumatra, is a highly specialised form, distinguished by elongate instead of rounded forewing, very sharply defined black margins to the greenish yellow upper surface of the wings and an apical spot on the forewing beneath reminding one of *sari* and *sodalis*, which is red-brown but traversed by a yellowish zone. But its specific distinctness remains nevertheless doubtful.

T. latimargo *Hopffr.* (= anguligera *Btlr.*) forms a transition to the *tilaha*-group inasmuch as the anal margin of the forewing above extends in North Celebes specimens to the middle of the wing; on the other hand such a close relationship to *hecabe* is shown by the colouring of the ♀♀ (of which some recall South Philippine and others Malayan races) and the presence of 2 cell-dots on the forewing beneath,
nesos. that its specific right is still an open question. Four forms deserve mention: **nesos** *subsp. nov.* (73 e, f), with narrower black distal border and weaker black dusting on the upperside of the forewing. ♂ very large, much lighter yellow than North Celebes ♂♂. *nesos* inhabits the peak of Bonthain, where in February
sophrona. and March the two seasonal forms overlapped at an elevation of about 4000 ft. — **sophrona** *form. nov.* is the form of the plains, common near Macassar and at the waterfall of Maros; ♂♂ of smaller size, ♀ dark
latimargo. yellow without any dusting. — **latimargo** *Hopffr.* is the mountain form from North Celebes, darker in both
pylos. sexes. — **pylos** *subsp. nov.*, a well-defined island race with broader and more deeply excised margins to
othrys. both wings. Sula Mangoli. — **othrys** *subsp. nov.* has also a very broad, proximally pointed anal spot on the forewing and uniform distal margin, imperceptibly incised on the hindwing. This is the form which Semper figured as *vallivolans ab.* Philippines.

blanda. **T. blanda** *Bdv.* (73 e), whose specific right has often been questioned, is a distinct species, characterised by narrower wings and less broad distal margin throughout, and distinguishable from *hecabe* by 3 instead of 2 small transverse streaks on the under surface of the forewing. The latter is indeed somewhat inconstant, in specimens of the rainy season sometimes scarcely to be recognised, but on the other hand the form of the genitalia defines the species with precision. The valve of *hecabe* is distally (apart from three finger-shaped appendages) only provided with one long-produced, rounded point, but that of *blanda* bears a small corona of four sharp teeth. In the character of the pattern *blanda* varies as much as *hecabe*, the specimens of the rainy season beneath almost unmarked, those of the dry period sprinkled with red. Also the form *sodalis* occurs, and thus it came about that *hecabe* and *blanda* have been often confused, and even a part of the figures of *hecabe* in Moore's Lepid. Indica belong to *blanda*. — The larva is

likewise different from that of *heeabe*, lives on another food-plant, Wagatea spicata, and is of a green colour with strikingly large black head and an indistinct yellow lateral stripe. The pupae lie closely ranged together upon twigs, are darker than those of *hecabe* and almost entirely black. *blanda* is almost as widely distributed as *hecabe*, appearing only to be wanting at the eastern and northern limits of the latter's range. — **arsakia** *subsp. nov.* is the most northern offshoot as yet discovered. Both sexes very *arsakia.* large; distal border of the hindwing of the ♂♂ comparatively narrow; ♀ pale green-yellow with broad distal margin, deeply and uniformly dentate proximally. The dry-season form **aphaia** *form. nov.* is smaller *aphaia.* than the wet form, particularly in the ♂; ♀ almost without black bordering on the hindwing above and without the dense black powdering of *arsakia*. Distal margin of the forewing in the ♂♂ almost rectilinear; the under surface sprinkled with reddish. *arsakia* is not rare on Formosa in July and August, *aphaia* in March and April. — **acandra** *subsp. nov.* is the form from Hong-Kong, of which I have before me only the *acandra.* dry-season form taken at the end of October, which shows a darker yellow colouring and even narrower margins on the forewing than *aphaia*. — The Philippines produce a series of island races, of which **viselliia** *visellia.* *subsp. nov.* is the Luzon form, pale yellow, with the hindwing somewhat more broadly margined than *acandra*, — **mensia** *subsp. nov.* that of the central Philippines, of darker colour and with broadened bands; *mensia.* Samar, Leyte, Bohol. — **vallivolans** *Btlr.* is founded on the dark yellow, broadly black-margined dry- *vallivolans.* season form from Mindanao, of which **simulatrix** *Stgr.* constitutes a very large rainy-season form, broadly *simulatrix.* shaded with black. — **natuna** *subsp. nov.* is a race with almost uniform and only moderately broad distal *natuna.* margin and a quite light ♀, recalling that of *harina* in its colouring. — **silhetana** *Wall.* (73 c) was described *silhetana.* from specimens of the dry season; Butler named the rainy-season form, with somewhat broader black margins, especially on the hindwing, **heliophila;** Assam, Sikkim. — **davidsoni** *Moore* (73 c, 2, erroneously *heliophila.* *davidsoni.* named *silhetana*) is the race from South India, which most closely approaches certain *hecabe* in the striking extension of the marginal colouring. Examples from Tenasserim and Tonkin to Siam and Annam differ somewhat from South Indian specimens in the narrower markings on the wings. — **citrinaria** *Moore*, *citrinaria.* based on specimens of the dry season, designates the small, very similarly marked Ceylon race, of which *templetoni.* the names **templetoni** *Btlr.*, **uniformis** and **rotundalis** *Moore* refer to examples of the rainy season. — *uniformis.* **snelleni** *Moore* (*nom. nud.*) is here adopted for a stately, broad-margined race from Sumatra, Perak and *rotundalis.* probably also Borneo. — **blanda** *Bdv.*, whose name-type came from Java, has the markings almost *snelleni.* identical in both seasonal forms, narrow and almost rectilinear. ♀♀ are rare; one from Bawean has the *blanda.* distal marginal dusting on the upperside of the hindwing extended. Java, Engano, Bali. — **sanapati** *sanapati.* *subsp. nov.* is smaller, darker yellow, the black colour on the forewing almost confined to the apical part. Sumbawa, Lombok, Alor, Sumba (?). — **roepstorffi** *Moore*, based on specimens of the dry season, differs *roepstorffi.* from the Ceylon race in its larger size; and **cadelli** *Moore* is an extreme dry-season form without black *cadelli.* distal margin on the hindwing above. Andamans, Nicobars; the ♂♂ of both were originally described only from the Andamans and the ♀♀ only from the Nicobars. Should the Nicobar race differ it must be named anew. — **cantideva** *subsp. nov.* is a very small race of a dark yellow colour with much broadened *cantideva.* and very deeply excised distal margin to the forewing. Wetter. — With **cungata** *subsp. nov.* begins a *cungata.* series of forms which again approximate to the Philippine type *vallivolans Btlr.* in their specially elongated wing-contour. The marginal band is narrow and very regular; ♀ differing but little from the ♂, basally only lightly dusted over with black. Amboina. — **indecisa** *Btlr.* is the deeper yellow, somewhat more *indecisa.* broadly margined race from the Northern Moluccas: Halmaheira, Ternate, Mangoli; Waigeu, New Guinea. — From Celebes no representative of *blanda* is yet known, but one may be confidently looked for, as also from Palawan.

T. moorei *Btlr.* is an interesting island form belonging to the *blanda*-group. Following the example *moorei.* of Bingham, it is here treated as a species; it is, however, not impossible that it is only a modified rainy-season form of *blanda*, so much the more as a dry-season form of it has not yet been found. In any case it occurs together with the above-named *roepstorffi* and *cadelli* on the Nicobars, is of medium size, dark sulphur-yellow with moderately broad, proximally finely dentate distal margin to the forewing. The hindwing bears only a narrow distal band. — **amplexa** *Btlr.* is only a local form of the same with the *amplexa.* marginal band somewhat narrowed on the forewing and widened on the hindwing. Christmas Island.

With **T. andersoni** *Moore* begins a series of species which only show a black ring-spot on the under- *andersoni.* side of the cell of the forewing. *andersoni* has the wings shaped like those of *blanda*, but is at once recognised by the much broader, deep black distal margin of both wings, which is proximally especially sharply dentate, and by its peculiar dark green-yellow coloration. Beneath it approaches *tihala Horsf.*, from Java, in the strongly expressed black dots and a row of submarginal spots united into bands. The species is everywhere very rare; the name-type comes from the Mergui Archipelago. Bingham knows it from Tenasserim and the Andamans and there is a ♀ from Assam in his collection. — **godana** *subsp.* *godana.* *nov.* is the most northerly branch known; larger than the type, more narrowly margined with black, somewhat paler yellow. ♀ but a little paler than the ♂, with delicate brown tinge on the hindwing beneath, especially in the dry-season form of April with sharply defined black marginal dots on the fore- wing. Rainy-season form taken in July, near Taihanrohu, Formosa. — **udana** *subsp. nov.* is the most *udana.*

southerly race, similar to the type in size, but the ♀ has the black-brown margins of the wings nearly three times as broad. The under surface of both sexes even more distinctly spotted with black than in the more northern forms. West Java, very rare.

lacteola. **T. lacteola** *Dist.* (73 d) is closely allied to the preceding species in the pattern of the under surface, which in the dry-season form, especially in Javanese specimens, shows almost as large a red apical spot on the forewing beneath as *sari*, so that it is not inconceivable that *lacteola* is only an extreme form of *sari*. But as proof of this is still wanting on account of the rarity of this insect, *lacteola* is here treated as a species. The typical subspecies, described by DISTANT from Perak was taken by me in Annam and *toba.* Siam. — **toba** *Nicév.* may represent the Sumatran race, unless indeed it was only erected on a mountain *varga.* form of *hecabe*. Only 3 or 4 examples are known, among them one from West Sumatra. — **varga** *subsp. nov.* is the race from West Java, normally larger than the figure, but both sexes with narrower black *yaksha.* distal margin. — **yaksha** *subsp. nov.*, a well differentiated island form, with very narrow black distal margin to the forewing and the upper surface of both wings basally powdered over with black; Natuna Islands. — *ada.* **ada** *Dist.* is the name of the Borneo form, very nearly allied to the Malayan race; the ♀ is figured on *prabha.* pl. 73 d. — **prabha** *subsp. nov.* differs from it in having the margins of both wings twice as broad and a richer yellowish tinge on the upper surface of the hindwing. Palawan.

T. sari is a species easily recognisable by its rounded wings, the large red-brown subapical spot in the cell of the forewing beneath, and by the single black ring-spot near the base. Its area of distribution is much less extended than that of *hecabe* and *blanda*, and scarcely extends beyond the true Malayan countries. The species is said also to occur in South India and Ceylon, but we have not received specimens *sodalis.* from there. — **sodalis** *Moore* is a local race with pale yellow ground-colour, the black distal margin of the ♀♀ being narrower than shown in the figure. Mergui Archipelago, Tenasserim, Malay Peninsula, Lingga *sari.* Archipelago, Sumatra. — **sari** *Horsf.* (73 f) is the typical subspecies, which occurs on Java, especially at elevations of 1000—2000 ft. in coffee-plantations overgrown with weeds or at the edges of woods. — *thyreus.* **thyreus** *subsp. nov.* is a specialised race with more extended black distal margin to both wings and especially copious red-brown ornamentation on the under surface of both wings. Island of Engano, common, *obucola.* in April. — **obucola** *subsp. nov.*, from South Borneo, Natuna and Palawan, has still broader black-brown *sarilata.* margins on the hindwing. — **sarilata** *Semp.* (= mindorana *Btlr.*) is a pale yellow race with moderately *crinatha.* broad margins from the central Philippines. — **crinatha** *subsp. nov.*, from the South Philippines, is, like all the forms from there, essentially darker: ♀ densely dusted with black and the distal margin still broader *curiosa.* than in Borneo examples. Mindanao. — **curiosa** *Swinh.* is according to BINGHAM an aberrant form of *sari* with unusually broad black distal margin. Bombay district.

lombokiana. **T. lombokiana** *Fruhst.* (73 d) recalls *sari* in the colouring, the shape of the wings and the black markings of the under surface, but the red apical spot is wanting on the underside of the forewing, the terminal margin of which has a complete black border, while in *sari* there are only red isolated distal dots. Lombok, May—June at elevations of 2000 ft.; Flores, in November. Everywhere rare, and may certainly be looked for also from Sumbawa and perhaps Timor.

invida. **T. invida** *Btlr.* is a species of uncertain position, which is rare in collections. BUTLER has since united it with *alitha Fldr.* as a dry-season form, SEMPER, who had larger material at his disposal, calls attention to its relationship to *tilaha Horsf.* and *latimargo Hopff.* Certain it is that *invida* occurs on Mindanao in two seasonal forms, and that it may perhaps be taken as the Philippine representative of *samarana.* *tilaha Horsf.* — **samarana** *subsp. nov.* is distinguished by a roundish, isolated patch at the hindmargin of *leytensis.* the forewing, such as is shown by no other *Terias*. Island of Samar. — **leytensis** *subsp. nov.* very nearly approaches *tilaha* in the continuous black anal margin of the forewing and the blackish basal tinge of the median vein of the hindwing. Island of Leyte.

T. tilaha is the most conspicuous of the Malayan species of *Terias*, which, although it also occurs near the coast, is found as a rule only at elevations of 1000—3000 ft. and prefers natural vegetation *tilaha.* rather than cultivated land. Three subspecies are known: **tilaha** *Horsf.* (= eumide *Fldr.*[1]) (73 g), of light yellow ground-colour; distal margin of the hindwing of the ♀ scarcely appreciably broader than in the ♂: *nicevillei.* ground-colour somewhat paler. East and West Java. — **nicevillei** *Btlr.*, of dark yellow ground-colour; *gradiens.* distal margin of the ♀ distinctly broader than in the ♂. Sumatra. — **gradiens** *Btlr.* (= rahel *Stgr.* nec *Fabr.* nec *Btlr.*). Distal margin of both wings very broad in both sexes. Hindwing of the ♀ distinctly *garama.* rounded off anally; North Borneo. — **garama** *subsp. nov.* has more elongate forewing, light yellow ground-colour and very narrow bands. Sulu Islands, Jolo Archipelago.

tominia. **T. tominia** *Vollenh.* (= tondano *Fldr.*) is perhaps only the strongly modified Celebes local form of the preceding species; the two have in common the black anal margin of the forewing beneath which is not found in any other *Terias*, and is apparently a secondary sexual characteristic, as it is otherwise common in ♂♂. But the shape of the uncus and valve is well differentiated, the distal valvular process

[1]) Confirmed by comparison of the types.

bearing in *tominia* two sharp points, whilst in *tilaha* (*gradiens*) it is rounded off laterally. Quite a series of local forms are already known and a large number may still be looked for from the small islands near Celebes. — **mangolina** *subsp. nov.* (73 h) has the border at the hindmargin of the forewing only somewhat narrower, whilst the ♀ only differs from *tominia* in having less yellow on the hindwing. Sula Mangoli. — **besina** *subsp. nov.* is a much smaller melanotic island race, with still more rounded wings and even more darkened in the ♀. Sula Besi. — **talissa** *Westw.* only differs slightly from *tominia* in the female, the ♂♂, however, bear a much broader and more obliquely placed band. Island of Talisse, off the north point of Celebes. — **tominia** *Vollenh.* has its name from the Gulf of Tomini in North-East Celebes, where, as well as in Minahassa and southwards to Toli-Toli, it is not rare, and was observed by me at the edges of the woods near the coast. The ♂♂ are apparently very constant, ♀♀ of the rainy-season form very large, with the yellowish band on the forewing sometimes very much narrowed. ♀♀ of the dry-season form as they occur in Central Celebes and in the south of the island, essentially smaller, with the yellow oblique band only slightly dusted over with black. — In South Celebes occurs a further distinctly defined mountain form: **battana** *subsp. nov.* (73 g), which is noticeable for the considerable reduction of all the black marginal bands and the predominance of the yellow ground-colour without black dusting. Peak of Bonthain, February, March, not rare at about 5000 ft. — **toradja** *subsp. nov.* is an intermediate form, in which the yellow oblique bands of the forewing are almost entirely suppressed by the black distal margin and the yellow band of the ♂♂ is much more obliquely placed. East Celebes. Named from the Toradja, the natives of the island. — **halesa** *subsp. nov.*, from Saleyer, may be recognised by a black anal border extending to beyond the middle of the cell of the forewing and a shorter yellow oblique band. — **faunia** *subsp. nov.*, from Binungka, approaches *besina* in its smallness and in the very narrow distal border of both wings, but has a paler ground-colour than all other named subspecies. — Finally, **arsia** *nom. nov.* (= snelleni *Fruhst.*), from Tanah-Djampea, again approaches *battana*, from which it differs by the black anal border encroaching more deeply on the cell. — **horatia** *subsp. nov.* (73 g) apparently replaces *tominia* on Borneo. This is one of the rare cases where Borneo and Celebes have a species of butterfly in common. Butler believed that he had identified *horatia* with *rahel F.*, a conclusion which cannot be justified from the inadequate diagnosis of Fabricius. Pontianak, South Borneo.

mangolina. *besina.* *talissa.* *tominia.* *battana.* *toradja.* *halesa.* *faunia.* *arsia.* *horatia.*

T. alitha *Fldr.* approximates to the figured *marosiana* and is easy to separate from the *tominia*-series by the elongated, narrow wings. According to Sempfr the ♂♂ remain very constant, whilst the ♀♀ are somewhat variable in the breadth of the distal border and also in the intensity of the ground-colouring. Observations as to seasonal forms have not yet been made. Sempfr figures a ♀ almost entirely black above. — As **bazilana** *subsp. nov.* we introduce here an island race with very broad distal margin to both wings, proximally very sharply defined. The anal border of the hindwing reaches nearly to the cell. Together with it occurs a form of the ♂ with the terminal band of the hindwing much narrowed anally and ending in a fine point at the submedian (f. **aebutia** *form. nov.*). Bazilan. — As **sangira** *subsp. nov.* I characterise a race in which the yellow oblique band of the forewing is reduced to half the width of that of *bazilana* and the hindwing shows a basal black tinge as extended as in *zita Fldr.* (73 h). Sangir. — **lorquini** *Fldr.*, from North Celebes, of which I have been able to compare the type, remained unknown to me in the field. The ♂♂ are smaller than those of **marosiana** *subsp. nov.* (73 g), whose ♀♀ have the upper surface of the wings finely dusted with grey-brown. — In **djampeana** *Fruhst.* the black distal border of the forewing enters the cell and also the hindwing is more broadly margined with black. Tanah Djampea.

alitha. *bazilana.* *aebutia.* *sangira.* *lorquini.* *marosiana.* *djampeana.*

T. zita *Fldr.* (73 h) so closely resembles *lorquini* in the male that we leave the question open whether they do not represent respectively the rainy-season and dry-season forms of a single species. The shape of the wings and the different scheme of marking in the ♀♀ are, however, very distinctive. On the island of Lutangan, near Toli-Toli I took a ♀ with the forewing entirely black and a remarkable dwarf form with yellow transverse bands, but almost entirely covered by black dusting, on both wings (**zamida** *Fruhst.*), which appears to form a transition to *lorquini Fldr.*

zita. *zamida.*

T. norbana *Fruhst.* (73 h) is noticeable for the sharply dentate bordering of the wings, which on the hindwing is proximally broken up into fine atoms. The species is very common at the borders of the woods at the coast of Toli-Toli, North Celebes. The ♀ only differs slightly from the ♂ in having the cell of the forewing lightly dusted with red-brown. — **odinia** *Fruhst.* (73 h) is a local form from southern Celebes, of larger size, but nevertheless with less and much lighter brown margining, in the ♀♀ of which the distal border of the hindwing begins to be broken up into spots already behind the middle of the wing, moreover on the forewing there is no dusting of the grey-brown scales. *odinia* occurs from the plain up to 5000 ft., from November to March. — **salegos** *subsp. nov.* is but a little more narrowly margined with black on the forewing than *norbana*, but the hindwing bears only a slight distal border, which is sharply defined proximally. Northern Moluccas: Halmaheira, Batjan. — In **anios** *subsp. nov.* the distal border is again somewhat widened and has on the hindwing distinct undulate excisions. Obi. — In **depicta** *subsp. nov.* the bordering of the forewing at the hindmargin scarcely reaches to the middle of the

norbana. *odinia.* *salegos.* *anios.* *depicta.*

wing and on the hindwing it is only distinctly noticeable near the median vein. Amboina. apparently everywhere rare.

T. celebensis is a pretty species, distinguished by the almost round hindwing and by the black margining in the ♂ occupying almost the whole distal half and in the ♀ commonly entirely suppressing the yellow on the upper surface. Rather rare and apparently inhabiting only the plains. It is divided into four geographical races: **exophthalma** *subsp. nov.* (73 f). Forewing also beneath with a submarginal row of strong black dots. Sula-Mangoli. — **poetelia** *subsp. nov.* ♀ with yellowish disc on both wings, which, however, is densely powdered over with black-brown. Sula Besi. — **celebensis** *Wall.*, from North Celebes. The black distal margin of the ♂♂ extends nearly to the apex of the cell on the forewing. ♀ entirely black-brown. Toli-Toli, November and December, rare. — **toalarum** *subsp. nov.* The distal margining is far from the apex of the cell on the forewing and extends on the hindwing to the cell-wall. ♀ with large discal yellow patches. South Celebes, named from the primitive inhabitants of the island — the To-ala — who to-day still live in caves.

exophthalma. poetelia. celebensis. toalarum.

T. candida, a well defined species, inhabits exclusively the Papuan region and the Moluccas with an offshoot towards Micromalayana. Boisduval mentions it also from Celebes. — **libera** *subsp. nov.* (73 d) is the largest known race. The ♀ differs from all the known forms in the light greenish yellow tinge on the upper surface of both wings. On 73 h *puella* is printed by oversight instead of *libera*. Northern Moluccas: Halmaheira, Batjan, Ternate. — **dindymene** *subsp. nov.* (73 c) may be recognised by the proximally strongly widened black anal margin of the hindwing, which near the cell is broken up into separate clusters of scales, and by the more extended black basal dusting on the forewing. Obi. — **candida** *Cr.* is the typical subspecies of the Southern Moluccas. Distal margin only a little narrower than in *dindymene*. ♀ white with dense brown dusting in the basal area of both wings. Amboina, Ceram, Buru, Saparoea. — **goramensis** *subsp. nov.*, from Goram, has much narrower black distal margins and forms a transition to **virgo** *Wall.* — The latter is a form with the ♀ entirely white. Aru Islands. — **papuana** *Btlr.*, with somewhat broader black distal margin than *virgo*. Misol. — **octogesa** *subsp. nov.* Distal border somewhat narrower than in *libera*. ♀ with intensively lemon-yellow tinge proximally to the black marginal band. Waigeu. — **puella** *Bdv.* has a white distal band, much widened especially towards the costa. Dutch New Guinea, from Humboldt Bay and Dorey to Etna Bay and Merauke. — **diotima** *subsp. nov.* ♂ lighter yellow than in the preceding, ♀ even purer white with appreciably narrower distal border to both wings. German New Guinea and Vulcan Island. In Australia and on the Fergusson Islands occurs a further subspecies of somewhat larger size. — **xanthomelaena** *Godm.* approaches *dindymene* in the ♂ through the anal margin of the hindwing extending to the cell. The ♀ is on the forewing densely dusted with brown-black to about the middle of the cell, on the hindwing in the entire distal half. Bismarck Archipelago. — **digentia** *subsp. nov.* differs from specimens from New Mecklenburg and New Pomerania in the much broader black distal margin of both wings (which forms a transition to *salomonis*) and the slighter black tinge on the hindwing and the lighter ♀♀. — **salomonis** *Btlr.* has relatively narrower black distal margin to both wings than the preceding. Length of the forewing 22—27 mm. Fauro and Alu Islands. — **woodfordi** *Btlr.* is said to have a yellowish instead of white ♀ and to recall *candida Cr.* in the shape of the distal margin. Length of the forewing 17—25 mm. Guadalcanar, Maleita and Florida; Shortlands. — Finally, **micromalayana** *subsp. nov.* is a very broadly black-margined race from the small Sunda Islands, of almost the same size as *libera* from the Northern Moluccas, which Boisduval already knew from Timor and which is represented in my collection from Flores. A representative of *candida* also occurs in Celebes according to Boisduval and Ribbe, but the species has not been recently found there. — According to Hagen the butterflies are common in New Guinea the whole year round, but only in the woods, never in open fields. Weak, unsteady flight, not far from the ground. *candida* differs from the other *Terias* by the longer fork formed by subcostals 3 and 4 on the forewing.

libera. dindymene. candida. goramensis. virgo. papuana. octogesa. puella. diotima. xanthomelaena. digentia. salomonis. woodfordi. micromalayana.

23. Genus: **Gandaca** *Moore.*

Moore founded on the collective species *harina* the above-named genus, without giving any differential characters, only erecting it *brevi manu* on the wing-contour, which differs somewhat from that of other *Terias*. Although the neuration of the forewing presents no difference worth noticing, on the hindwing the elongate instead of short and broad shape of the cell is conspicuous and the subcostal arises far before the apex of the cell, so that a very long upper discocellular is formed, which in the rest of the Indian *Terias* is absent resp. shortened. Moreover, the cell-wall is bent distad and not proximad. The genus embraces only one known species.

G. harina *Horsf.* (73 c) has the same habits as *candida* and is met with only in woods, never in abundance, visiting flowers, and sometimes resting on the same flowers with Zemeros- and Lycaenid-♀♀. *harina* flies all the year round, from the sea-shore up to 2—4000 ft. The species has about the same

harina.

range as *hecabe*, but is very constant in any one locality, yet almost more inclined than even *hecabe* to local variation at short distances. — **hainana** *subsp. nov.* has the ♀ entirely pure white with very narrow black distal border to the forewing. Hainan. — **gardineri** *subsp. nov.* Both sexes lightish yellow, ♀ with very broad apical margin to the forewing, deeply dentate proximally. February, March. Island of Bazilan. — **mindanaensis** *Moore* (*nom. nud.*) has like the ♀ of all the other Philippine races a tendency to vary from yellowish white to light ochre-yellow and that independently of the locality. The variation is most probably seasonal. Flies principally in May and October. South Philippines. — **palawanica** *Moore* (*nom. nud.*) has, according to specimens in my collection, a somewhat more restricted black apical tinge on the forewing than *gardineri*. Palawan, January, February. — **elis** *subsp. nov.* has a white ♀ with strikingly broad, strongly dentate border on the forewing. North Borneo. — **distanti** *Moore* (*nom. nud.*) with light yellow ♀♀, which of all known races bear the broadest and at the same time the least dentate distal border. Malay Peninsula, Sumatra, Nias (?). — **burmana** *Moore* (= annamica *Moore i. l.*), distributed from Tenasserim to Siam and South Annam, is in the ♂ not even seasonally variable (January and then again August, September), with moderately wide apical border; ♀♀ yellowish white and proximally scarcely dentate. — **assamica** *Moore* may be at once recognised by the black colour on the forewing being narrowed to a fine distal border, which is also not widened in the white ♀♀. Sikkim, Assam, Bengal. — **andamana** *Moore* is a large race with moderately broad marginal colour in both sexes. Andamans, Nicobars. — The typical **harina** *Horsf.* (73 c) is described from Java. ♀ white, similar to the form from the Andamans. In the east and west of the island up to 3000 ft., never common. — **austrosundana** *subsp. nov.* has in both sexes a narrower distal border, which in ♂♂ of the dry-season sometimes almost disappears. Lombok, May and June in dense woods at elevations of 2000 ft. — **samanga** *subsp. nov.* (73 c), as is so often the case in Celebes races, is the largest known subspecies, ground-colour slightly greenish yellow with the distal margin of the forewing broken up into fine teeth. November, South Celebes. — **auriflua** *Fruhst.* (73 c), of orange-coloured tint, is peculiar to the Sula Islands, where the yellowish *Salatara panda* of all the neighbouring islands likewise assumes a reddish tone. Together with reddish resp. dark yellow ♂♂ there occur also both on Sula Mangoli and Sula Besi light sulphur-yellow specimens. — **aiguina** *subsp. nov.* appears to be distributed from Obi, in the Southern Moluccas, to Waigeu and New Guinea. The ♂♂ have but little more apical black than those of *auriflua*, the distal border of the ♀♀ contains numerous indentations proximally on the forewing and is continued on the hindwing as a distinct marginal band. — **butyrosa** *Btlr.* has an unusually narrow black distal border on the forewing. Aru Islands.

hainana. *gardineri.* *mindanaensis.* *palawanica.* *elis.* *distanti.* *burmana.* *assamica.* *andamana.* *harina.* *austrosundana.* *samanga.* *auriflua.* *aiguina.* *butyrosa.*

G. impura *Voll.*, described from Timor, is unknown to us in nature; according to VOLLENHOVEN'S figure it may possibly be placed here. *impura.*

24. Genus: **Teracolus** *Swains.* 1823 [1].

A bicontinental genus the home of which is Africa, and which has reached Anterior India along the Persian Gulf, and perhaps across a Lemurian bridge of the Tertiary period. 8 species occur in South India as against about 60 or 70 in Africa and not one of them extends further east than Ceylon and Central India. In neuration *Teracolus* approaches *Terias* and just as in the latter there are groups of species with longer or shorter upper discocellular according as the 1st subcostal arises before or at the apex of the cell. The subcostal of the hindwing is sometimes closely approximated to the costal. Larva very similar to the *Terias*-larvae. The apex of the precostal of the hindwing as in *Pieris* and *Hebomoia* bent outwards, prolonged into a fine point. The hot lowlands of India with their long dry period and some districts of northern Ceylon with their paucity of vegetation offer them suitable conditions; all the species are horodimorphic, and most also sexually dimorphic; geographical and insular races likewise exist, but the former are not easy to define.

T. amata *F.* Very common in India with the exception of Bengal, in the whole of Arabia, Madagascar and eastern Africa as far as the Congo. — Larva cylindrical or laterally slightly compressed, the upper surface rough owing to numerous small tubercles bearing small points. Ground-colour grass-green with blue dorsal line and a yellowish lateral line. Pupa with keeled wing-cases, brownish or dirty green, otherwise similar to those of *Terias*. — **modesta** *Btlr.* (73 b) is the race from Ceylon, widely distributed in collections, whose ♀♀ occur in 2 forms with salmon-coloured and whitish upper surface. The species is nowhere rare at the artificial lakes in the north of Ceylon along the main road towards Trincomali at the edge of the woods, tireless in flight, but like all its congeners only flying in hot sunshine. Larva on Salvadora persica.

amata. *modesta.*

T. protractus *Btlr.*, a species first figured in 1898, is above coloured similarly to *amata* with black distal border to both wings, which are ornamented with blue-grey patches. Under surface gorgeous green-yellow. From Baluchistan, Punjaub to Cutch. *protractus.*

[1]) *Colotis Hbn.* 1816 has priority. Synonyms are *Callosune Dbl.*, *Idmais Adv.*, *Madais Swinh.*

phisadia. **T. phisadia** *Godt.*, already discussed in the Palearctic part, p. 57, and figured pl. 23 a. — Pupa pale brown, spotted with darker brown, head with very sharp point, wing-cases only slightly keeled. Very rare in the Punjaub, where it only appears now and then, like a wandering bird of passage.

vestalis. **T. vestalis** *Btlr.* (73 c), nowhere rare at the Persian Gulf, occurs in two sharply separated seasonal forms, that of the summer (rainy season) light yellowish, that of the winter (dry season) reddish with *peelus.* sand-coloured powdering on the hindwing beneath. — **peelus** *Swinh.* is an aberration with light canary-yellow upper surface.

fausta. **T. fausta** *Oliv.* This magnificent Palearctic butterfly (vol. I, p. 56, pl. 23 c) inhabits the countries around the Persian Gulf from Baluchistan to Bombay, and in Central India passes gradually into the race *fulvia.* **fulvia** *Wall.* (= tripuncta *Btlr.*), which is somewhat darker yellow. — The larva has not yet been found in India. The butterfly is very rare in Ceylon, where it flies near Trincomali and Manaar in January, is *palliseri.* very shy and does not settle again when once it has been frightened. — **palliseri** *Btlr.* is an extreme dry-season form.

etrida. **T. etrida** *Bdv.* approaches the African *daira Klug.* The rainy-season form **etrida** *Bdv.* (73 b, to which belongs also the ♂ figured as *purus*, 73 b 3) has the usual broad black bordering to the red sub-*purus.* apical spots of the forewing and the ♀ is above strongly dotted with black. The winter form **purus** *Btlr.* (73 b 4) with paler red on the forewing and the black on the upperside of both wings obsolescent. — Larva strongly prolonged anally, uniformly green with yellowish or variegated lateral line above the legs and does not fasten the anal end to a twig (Davidson). Pupa with the snout curved upwards, first greenish, then grey-white, very beautifully sprinkled with brown. Baluchistan, Kashmir, the whole of *limbata.* Anterior India with the exception of Bengal. — **limbata** *Btlr.* is the race from Ceylon, which is somewhat more prominently marked with black. The butterfly is fond of floating with the wind over the plains covered with high grass; it occurs all the year round and is not rare near Trincomali.

danaë. **T. danaë** *F.* is the most imposing of the Indian *Teracolus*, yet cannot compare with the magnificence in colouring of its African relatives. The variability of the species exhibits interesting gradations; we have figured the rainy-season form; but there are also ♀♀ almost without red on the forewing and others with yellow bordering proximally to the black submarginal band of the forewing. ♀♀ of the dry season have no proximal black bordering to the ornamental spot of the forewing and this is also reduced in the dry-season ♂♂. The latter are also without the black dots, sometimes with beautiful red centres, on the underside of the hindwing, which assumes a sand-coloured tone, slightly tinged with rose-colour *subroseus.* (**subroseus** *Swinh.*). An intermediate form Butler named **sanguinalis** and the extreme dry-season form *sanguinalis. taplini.* is **taplini** *Swinh.* Persia, West and South India, common; very rare and local in Ceylon.

eucharis. **T. eucharis** *F.* (73 b) may be easily recognised by the yellow instead of red subapical spot of the *pallens.* forewing. ♀ of the rainy season with strong, that of the dry season (= **pallens** *Moore*) with weak, black dotting and rose-red instead of yellowish underside to the hindwing. — Larva on Cadaba indica, a Capparidea. The butterfly appears in Ceylon in June, then again in December, and flies in warm sunshine, also on the bare, wind-swept sea-shore. Common in Bengal, also distributed from Central India to Kanara.

25. Genus: **Hebomoia** *Hbn.*

The largest Asiatic Pierids constitute this genus, which unites in itself the characters of three genera, *Catopsilia*, *Antoeharis* and *Eronia*, having in common with the latter the form of the palpi and the two free radials. Antenna long, entirely without club and only thickened gradually towards the tip. Four subcostals, of which the last two form a short fork. Precostal as in *Teracolus*; cell of the hindwing elongated, upper discocellular long. — Larva on Capparis, very similar to those of *Catopsilia*, thick, narrowed at both ends, green with pale lateral stripes and shagreened upperside. Pupa canoe-shaped, produced at each end into a long point. The genus only embraces two species, which are distributed over the whole of South Asia and show a tendency to the development of well separated island races. Of especial interest zoogeographically is the contrast between the *glaucippe*-branches of the Andamans and Nias, which are of a relatively uniform colouring, contrasting sharply with the continental Indo-Sumatran region, and the wide differences between *leucippe* from the Southern and *glaucippe* from the Northern Moluccas. The former phenomenon might be explained by the connection of the Andamans, Nias and Mentawej in tertiary times. The snow-white or yellow butterflies with brilliant red spot are quite an ornament to the tropical landscapes. The ♂♂ mostly fly in the morning and remain at the edges of paths and woods and in open thickets. In Ceylon, Java and Tonkin I found them drinking at Lantana flowers. Not until the middle of the day do they settle on moist sand. The ♀♀ do not usually fly far and are rather sluggish; they prefer to remain in the thickets, from which, for instance in Celebes, I beat them out

early in the morning with a stick. The ♂♂ also congregate at wet places, particularly at river-banks, and can be attracted by making artificial pools at the edges of woods. When the Hebomoias are resting they push the hindwing forwards so that the whole base of the forewing is entirely covered and the grey-scaled apex adjoins the margin of the hindwing with its uniform sand-coloured powdering. In this way the butterflies are well adapted to their surroundings.

H. glaucippe *L.* occurs everywhere in two seasonal forms, the winter form (dry season) consisting *glaucippe.* mostly of much smaller specimens (70 b ♂♀) with pointed apex and light sand-coloured under surface in both sexes. The summer brood (rainy-season form), of more imposing size, has a broad, black proximal bordering to the apical spot of the forewing, moreover the hindwing as a rule is strongly dotted with black and the veins before the marginal band are black. In the dry-season form the black subapical band is narrowed and even commonly replaced by a yellow border, and the black colouring on the hindwing is reduced, if not altogether suppressed. In my largest ♂ of the rainy season the length of the forewing is 95 mm, in the smallest of the dry season 57 mm. *glaucippe* has a distally narrowed harpe with widely projecting upper point, at the base of which a relatively deep sinus is noticeable. The lower end of the harpe recedes strongly, producing a shape which recalls the head of a bird of prey. The species inhabits China, the whole of Further India and British India, and extends southwards to the Nilghiris. Also known from Hong-Kong and Hainan. — **liukiuensis** *Fruhst.* must be regarded as the most northerly geographical *liukiuensis.* branch of the species, and as on Okinawa the seasons are more noticeable than in the other subtropical and tropical localities of *glaucippe,* the most pronounced seasonal forms of the species are found there. The winter brood (70 c) is like a ♂ in colouring and distinguished by the sharply produced apex of the forewing. Time of flight February to March. Expanse up to 95 mm. f. **conspergata** *Fruhst.* (70 c), the *conspergata.* summer generation, is larger, has a usually broad, black distal margin and very large, wedge-shaped submarginal spots and the whole upper surface of the wings densely scaled with grey-blue. Time of flight from June to August. Expanse up to 112 mm. Okinawa, Loo Choo Islands. — **cincia** *subsp. nov.* differs *cincia.* from the preceding in the smaller black wedge-spots in the red patch of the forewing, which is much less bordered with black and recedes widely in front of the apex of the cell, so that a white transcellular area is formed, which is lightly powdered over with black and which no other race possesses to the same extent. Most southerly Loo Choo Islands, Ishigaki. — **formosana** *Fruhst.* is usually smaller than the *formosana.* preceding races, the ♀♀ approach the Chinese and Himalayan race, but appear to differ constantly from continental *glaucippe* in the dark greenish yellow colour of the upperside of the wings and the extremely broad, black subapical band on the forewing. Two broods, that of the dry season with the ♀♀ only lightly coloured with yellow above, and moderately black scaling. The rainy-season form (70 c) is in extreme specimens even darker yellow than the figure, with the forewing almost entirely blackened and still more extended black wedge-spots on the hindwing. The lightest examples taken at Taihanroku near the south coast of Formosa, one in March, the darkest in April. — **australis** *Btlr.* is the South Indian *australis.* race, from the Malabar and Coromandel Coasts; larva living on three species of Capparis and a Crataeva, dark green with a blue lateral line and a row of red spots. Pupa spindle-shaped, with strongly curved dorsum, likewise green with narrow ochre-coloured lateral band and a spot of the same colour on the wing-cases. Abdominal segments and wing-coverings further sparsely sprinkled with black. The butterfly has less black at the apex of the forewing than the typical subspecies from North India. — **ceylonica** *ceylonica.* *Fruhst.* (70 a) may be separated from *australis* by the much more delicate interneural black subapical streaks on the forewing and by having the ♀ widely suffused with a beautiful yellow in the discal part of the forewing. Larva green, covered with numerous small tubercles, strongly narrowed at both ends, hitherto only observed on Capparis. Pupa greenish, with pointed head and strongly curved dorsally. Butterflies common in the hill-country of Ceylon, also on sand-banks, and in Colombo and Kandy even a common visitor in the gardens. — **roepstorffi** *Wood-Mas.* (71 a) is the interesting race from the Andamans, *roepstorffi.* with yellowish tinge on the distal part of the hindwing in the ♂♂. — **vossi** *Maitland.* Nias, *Batu* (?) *vossi.* (71 a). It gives quite the impression of a separate species on account of its yellow colouring. But it is highly probable that on the satellite islands of Sumatra forms also occur which like *roepstorffi* are half white, half yellow. The yellow colour cannot be used as a specific character, for in *Ixias* there occur at a single locality all the transitional stages from white to yellow. „The whole insect looks on the upper surface like a large specimen of the Timor form, which has been dipped in a yellow dye and in which only the black parts of the wings, the antennae, the eyes and the brownish hairs of the head and patagia have retained their original colouring. I consider it not impossible that this yellow colour may be traceable to the food of the larva; an analogous case, among others, would be that of *Vanessa io L.*, of which it is said that by feeding with a certain plant, said to be a Solanum, a peculiar aberration inclining to bluish may be produced" (FRITZE). „*roepstorffi Wood-Mas.* from the Andamans and *vossi Maitland* from Nias are the only West Malayan *glaucippe*-forms with yellow upper surface to the wings. Both form a contrast to continental Indian and Sumatran races". This curious fact may possibly be explained, apart from climatic and ontogenetic influences, by the former connection of the Nicobars, Simalur, Nias and Engano. — **sumatrana** *Hagen* has the proximal black bordering of the orange spot considerably narrower *sumatrana.*

than in *borneensis*, the apical spot itself broader, adorned with somewhat larger wedge-spots. Not rare at about 1000 m. in the Padang Bovenlanden and in North-East Sumatra. ♀♀ are rarely brought to Europe.

borneensis. Flies principally in May, also March to August. — **borneensis** *Wall.* (70 d) is the most extended black race,

aturia. and its ♀♀ are much sought after as rarities. North and South Borneo. — **aturia** *subsp. nov.* is intermediate between continental and Sumatran specimens and differs from examples from Anterior and Further India in the more extended black distal colouring of the forewing and the darker red apical spot with more intensively violet sheen, the red colour of which reaches much further into the cell of the forewing. The black submarginal wedges on both wings larger, under surface darker. From Singapore to Tenasserim,

javanensis. where it passes gradually into *glaucippe*. — **javanensis** *Wall.*, a well defined island race, relatively small, wing-contour more rounded than in eastern and western allied forms. Distal margin broadly and sharply black, apical spot as in *aturia* extending far into the cell, submarginal patches of the hindwing in the ♀♀ very small. The species is common in East and West Java. Scarcely ascends above 3000 ft.; the ♀♀ are less rare than continental ♀♀, and especially than those from Sumatra and Borneo. Bali. — On

lombokiana. Kangean flies a race with much reduced red apical spot on the forewing of the ♀♀. — **lombokiana** *Btlr.* (70 c and d) is distinguished from *javanensis* by larger black circumscription to the red spots of the forewing, in the place of which there is a light yellow tinge. In Lombok I found both sexes at elevations up to 4000 ft. on the plateau of Sambalun. There the butterflies sailed along in the most brilliant sunshine and hung for minutes at a time on the most various flowers, seldom, however, settling on low

timorensis. plants, but this beautiful butterfly occurred also even near the seashore. — **timorensis** *Wall.*, from Timor

flavomarginata. and Alor, and **flavomarginata** *Pagenst.*, from Sumba, are distinguished by the complete absence of a black

anaxandra. submarginal band on the forewing, also the black wedge-spots are reduced. — **anaxandra** *subsp. nov.* has also no black bordering to the red ornamental spot, but very large submarginal wedge-spots on the forewing, and the red spot projects especially deeply into the cell of the forewing. Island of Kalao. —

celebensis. **celebensis** *Wall.* (70 d), by far the largest *glaucippe*-race, the ♂♂ of which surpass in expanse both *liukiuensis* and *leucippe Cr.* ♂♀. It is at the same time the only local race with polychromatic ♀♀. They are

icteria. as follows: ♀-f. **icteria** *Fruhst.*[1]) South Celebes, November, taken at the end of the dry season. Wings bluish white, apical spot pale sulphur-yellow. Hindwing narrowly margined with grey-brown. Under surface grey-white and with a yellowish subapical area on the forewing. Length of wing 50 mm. ♀-f.

principalis. **principalis** *Fruhst.* North Celebes, November—December 1895. Both wings broadly margined with brown-black. Cell of the forewing slightly tinged with violet-brown. Apical spot white with orange streaks or red-orange as in Indian ♂♀. Underside of both wings dusted with dark brown in the apical part. Length

sublustris. of the forewing 54 mm. ♀-f. **sublustris** *Fruhst.* Toli-Toli. Under surface and central part of the forewing like ♀-f. *principalis*. Cell covered with yellowish brown and grey. Hindwing blue-white with slight orange sheen at the costal margin. Apical spot white with red or yellow streaks. The latter form is before me both from North Celebes and from Sangi on Taruna (Talaut Islands). ♂♂ up to 111 mm expanse in the rainy form, ♂ of the dry form 95 mm. ♂♂ of *celebensis* enliven flowers or rest on moist sand to drink, whilst the ♀♀ remain hidden in the low brushwood. When I beat the bushes at the coast of Toli-Toli with the net-handle in the morning, especially on rainy days, ♀♀ came tumbling out shily from their hiding-places and could then easily be caught without exertion. North and South Celebes, Dongala,

sulaënsis. August—September. Dry form: Taruna, Talaut Islands. — **sulaënsis** *Fruhst.* ♂♂ with broader black distal

philippensis. margin on the forewing, ♀ with smaller submarginal spots on the hindwing. Sula Mangoli. — **philippensis** *Wall.* is a collective name for various island races, the differentiation of which has not yet been worked out. The divergence of the several forms from typical *glaucippe* is correlated to the geographical position.

erinna. North-West Luzon, West Mindoro, Babuyanes produce a *glaucippoid* race (**erinna** *subsp. nov.*), which occurs in a broadly black-margined rainy form (approaching *borneensis*) and a yellowish-tinged dry form (approaching *javanensis*). Mindanao and its satellite islands produce typical *philippensis*. Specimens from

sulphurea. Domoran, Bohol, Camotes and Mindanao form the transition to **sulphurea** *Wall.* from Batjan, whilst those from North-West Luzon, Mindoro and Babuyanes are closely allied to continental *glaucippe*, especially Chinese. Other ♂♂ again have the proximal black bordering of the orange apical spot almost as broad as in *borneensis Wall.*, facts which do not come as a surprise when we remember that the Philippines have been in close connection and interchange of species both with the continent and with Borneo and the

reducta. Moluccas through the bridges of land that intervene. — **reducta** *Fruhst.* is a race from Polillo, in which the ornamental spot of the forewing is reduced by almost half the extent which we find on other Phi-

palawensis. lippine forms. — **palawensis** *Fruhst.* ♂: the orange-coloured apical spot extends further into the cell of the forewing and is proximally almost without any black bordering. The submarginal spots smaller and more delicate than in *philippensis*. ♀: distal dentate band of the hindwing very narrow, deeply incised, becoming obsolete anally, the black submarginal spots placed before it more indistinct than in *philippensis Wall.*; orange

cuyonicola. spot of the forewing proximally without a trace of black bordering. Palawan, January. — **cuyonicola** *Fruhst.* The specimens from the small island of Cuyo differ most, as the under surface in the ♂♂ is not sprinkled with grey on a white ground, but quite as yellowish as in *rossi* from Nias, except that the proximal half is not so

[1]) Icterius = the jaundice.

sulphur-yellow as in the latter species. Some ♂♂ have above a yellowish tinge over the whole of the white ground, thus forming a transition to *vossi* (SEMPER). On the island of Cuyo, which lies between Palawan and Panay and is separated from the rest of the Philippines by deep channels. The fauna of this island contains a large percentage of Malayan elements, which reached the Philippines from Borneo by a former Borneo-Mindoro bridge of land, whilst conversely the Philippines have likewise furnished a number of species to Borneo and Celebes across the Mindanao-Sulu bridge. — **sulphurea** *Wall.* (70 b) is the geographical subspecies which is furthest removed from the true *glaucippe* and may almost lay claim to specific rank. Batjan. — **felderi** *Voll.*, from Halmaheira and Morotai, judging from the figure, we regard as a good local race, as Batjan examples show a much broader black border to the orange apical spot of the forewing than Halmaheira ♂♀. The ♀ from Batjan, moreover, appears to have always a yellow instead of red-yellow apical spot on the forewing. — **aurantiaca** *Fruhst.* differs from *sulphurea* in having the orange spot on the forewing almost twice as broad and enclosing only the rudiments of three isolated black wedge-spots, which in *sulphurea* are so large as to touch each other and form a dentate band. The distal black border of the forewing considerably narrower than in *sulphurea*, the costal margin yellow instead of black as far as the apex of the cell. Upper surface of the hindwing darker and more uniformly yellow. Obi. *sulphurea.* *felderi.* *aurantiaca.*

H. leucippe *Cr.* (71 a), a magnificent species, of which we know three subspecies. The shape of the harpe differs essentially from that of *glaucippe* and may best be described as canoe-shaped; the lower point is but little shorter than the upper, resp. the upper point only projects imperceptibly, and the depression at its base is scarcely noticeable, so that the outline is more simple and regular. *leucippe* inhabits Amboina and Saparoea. — On Ceram appears a branch-race, **daemonis** *Fruhst.* (71 b). Upper surface of the forewing much darkened, cell scaled with black to the middle, the area between radials and 1st median entirely black, as well as the whole anal region. Red submarginal spots much reduced, only the central ones distinct. Distal border and submarginal spots of the hindwing more extended black, underside of the hindwing whitish instead of yellow. — **leucogynia** *Wall.*, from Buru, is only represented in a few collections and one might be tempted to regard it as possibly a transition from *leucippe* to *sulphurea* and *aurantiaca*. The orange patch extending over the entire wing, which is so characteristic of *leucippe*, already begins to diminish in *leucogynia*, leaving the whole anal border and the base of the cell on the forewing of the original yellow ground-colour. The dark canary-yellow upperside of the hindwing of *leucippe* is likewise here lighter, and has even lost the brilliant yellow distal border peculiar to *aurantiaca Fruhst.* from Obi and *sulphurea Wall.* from Batjan. The under surface of the wings in *leucogynia* assumes altogether the character of the colouring of *sulphurea*, so that *leucogynia* apparently constitutes the transition from *leucippe* to *sulphurea*, whilst by its wing-contour and the different type of colouring from all the Hebomoias, *leucippe* gives the impression of a distinct species. *leucogynia* is, however, specifically far removed from *glaucippe sulphurea*, possibly a result of the geological isolation between the Southern and Northern Moluccas. *leucippe.* *daemonis.* *leucogynia.*

26. Genus: **Pareronia** *Bingh.*

This genus differs from all other Pierids in the five-branched subcostal of the forewing, but has the radials free as in *Hebomoia*. The precostal of the hindwing is rather steeply vertical, not bent outwards as in *Hebomoia*. The discocellulars of the forewing vary much in the different species, thus *avatar* has the middle discocellular strongly produced distally and sharply angled, whilst in *argolis* and *pingasa* it is gently rounded. Also the shape of the cell of the hindwing is somewhat variable, being very long and pointed in *avatar* and much shorter and narrower in *pingasa*.

The ♂♂ of some species are copiously provided with secondary scent-organs, those of *argolis* even recall Euplocas in the convex hindmargin of the forewing. All the ♂♂ have on the upperside of the hindwing at the subcostal and the central veins indistinct, dull mouse-grey patches of androconia, which in *tritaea Fldr.* and *jobaca Bdv.* especially form a broad furry coating, and in the latter are also present on the under surface of the forewing. These scent-scales are inserted by means of round knobs and belong to the *plumulae* (feather-scales) known to exist in many Pierids.

The ♂♂, although almost all of dull, pale blue-green colour, form, as a glance at pl. 66 and 67 shows, an assemblage of diverse forms as regards wing-contour, and in most of them there is a glossy area on the hindwing, which again recalls Euploeids. But however various the external shape of the ♂♂ may be, the pattern of the ♀♀ is throughout of the Danaid type, and there is no difficulty in assigning to each species a model whose colouring it has assumed. As, moreover, the neuration of *Pareronia* approaches the Danaids most nearly of any Pierids in the five-branched subcostal, the genus might also be regarded as a kind of connecting link between the two families.

The ♀♀ are as a rule dimorphic, sometimes even trimorphic, and species with trimorphic and monomorphic ♀♀ alternate geographically in a mixed and irregular succession, as e. g. in Anterior India

and on Java polymorphic ♀♀ occur, whilst in Malacca and Sumatra there is a species with monomorphic ♀.

Larva on Capparideae, cylindrical with two anal points, green with fine hairs and lateral white spots. Pupa pale green, wing-cases strongly projecting, snout very pointed. The ♂♂ have an erratic flight, hurrying from flower to flower, but never frequenting puddles. ♀♀ sluggish and so Danaid-like that they again and again deceive even the most experienced eye.

In the form of the genitalia *Pareronia* approaches *Catopsilia* in the broad, deeply incised valve; the form of the uncus is the same as in *Prioneris*.

According to the observations of Dr. Piepers the eyes of the living butterflies are blue-grey, at least in *valeria Cr.* from Java.

The genus has some brilliantly coloured allies in Africa and is distributed over the whole Indo-Malayan region and part of the Papuan territories.

P. avatar is entirely without androconia on the hindwing above; the ♀ recalls *P. nenocles Dbl.* in
tarina. the scheme of marking. The species occurs in two broods, of which the spring one, **tarina** *Fruhst.* (66 a), is characterised by the pale yellowish green ground-colour and occurs in March-April, whilst that of the
avatar. summer, **avatar** *Moore* (66 a), occurring from June to November, is noticeable for the broader black borders and larger size. The ♀ of the rainy-season form (pl. 66 a 3 misprinted *sumbawana*) is densely dusted with black especially on the forewing, a transitional form has the veins less broadly black and the ♀ of *tarina* is still unknown. All have in common a specially bright mother-of-pearl gloss on the under surface of the hindwing and the apical area of the forewing. Sikkim, Assam ascending from 1000 to 5000 ft. —
paravatar. **paravatar** *Bingh.* (66 a) is remarkable in the ♂ for the broader black distal border of the hindwing, in the ♀ for the larger white submarginal ovals on both wings around the extended black-grey tinge on the upperside. The under surface of the hindwing is likewise darker. Tenasserim.

P. valeria is a widely distributed species, with an incredible capacity for forming modification within short geographical distances and on all the islands where it occurs from the Philippines to the Andamans and Micromalayana. The ♀♀ occur in 2—3 dimorphic forms, very rarely in one only. The species is everywhere common, yet the earlier stages have apparently not yet been described, but are known of a closely allied South Indian form (*pingasa*), which has hitherto been allowed specific rank, but is perhaps only a highly developed rainy-season form. The ♂♂ are tolerably constant. They are swift fliers and do not rest long, but are fond of frequently changing the place where they settle. But the ♀♀ by their sluggish flight resemble the Danaids to such an extent that in Tenasserim I was constantly taking them for *Danais grammica*, often as they had already deceived me. In Sumatra and Java the yellow ♀♀ mimic the likewise yellow *Danais aspasia* and *philomela*, but yellow ♀♀ also occur in South India, where there is no yellow Danaid model, and we observe an analogous case in *luceria* from Waigeu, in which grey and yellow ♀♀ likewise occur, to which latter the Danaid model is wanting on that particular
hippia. island. — **hippia** *F.* is the continental branch of the species, which occurs very commonly on the southern peninsula, but becomes more rare towards the north and in Sikkim-Terai (the hot outlying valleys of the Himalayas) is only found in very small numbers. We have figured an extreme dry-season form (66 c ♂; b ♀), which Felder has described as *gaea*. In addition a rare form of the ♀♀ was already made known by Fabricius and Donovan, with brilliant, intensive orange-yellow tinge on the cell and anal part
philomela. of the hindwing (**philomela** *F.*). Distributed from South India to Assam, Burma and Siam. Swinhoe has recently figured the larva and pupa, which were discovered by Aitken and Bell. Larva on the same plants as that of *pingasa Moore*, green, but the tails more widely separated by a quadrate interspace. Pupa of very remarkable shape, with the dorsal distal margin shaped like an enormous sun-helmet, snout pointed, at its base a black patch, the segments ventrally striped with black, finely dotted with black. —
persides. In Tonkin occurs a larger race, with broader black bands in the ♀: **persides** *Fruhst.* (66 b), of which the
livilla. yellow ♀-form (**livilla** *Fruhst.*) shows a slight yellowish suffusion on the hindwing only in the basal portion of the cell. In Annam I obtained further an intermediate form, similar to *Pap. macareus*, with relatively broad whitish stripes on the upper surface of both wings, which approaches the *hippia*-♀ (66 b), similar specimens also occurring in Lower Burma, whilst *livilla* is occasionally found also on the Malay Peninsula.
lutescens. There *livilla* occurs together with **lutescens** *Btlr.* (66 c), originally described from Borneo, but also found in Perak and the whole of Sumatra. The yellow colour on the forewing of the ♀♀ often enters the cell. The ♀♀ of *lutescens* are rare, not being known as yet from the Malay Peninsula; the ♀♀ from Sumatra a
niasica. little lighter yellow than those from Borneo. — **niasica** *Fruhst.* has in the ♂ scarcely any yellowish tinge on the underside of the hindwing, on the other hand the much broader transverse bands — also on the forewing — are without exception light yellow and only the very large submarginal dots remain white. Nias;
valeria. a similar form may probably be looked for also from Batu and the Mentawej Islands. — **valeria** *Cr.* (66 b) bears broad white transcellular bars on the forewing. The yellow tinge does not enter the cell of the forewing in the typical race from East Java. West Java produces a larger *valeria*-race than the east of the

island. I formerly regarded this West Javan subspecies as a rainy-season form of true *valeria*. But I have since convinced myself that *valeria* does not differ in East Java seasonally, but remains constant all the year round, and hence I have given the western form a name as „**leona** *Fruhst.*". As already mentioned, *leona* is larger than *valeria*, with narrower wings, moreover the ground-colour of the ♂♂ is lighter on both sides. The hindwing in comparison to its size is more narrowly margined with black. The principal character, however, is in the subcostal vein of the hindwing, which is scarcely blackened, while in *valeria* it is broadly and densely covered with black scent-scales. *valeria* has this character in common with all the more easterly races, *sundana*, *sumbawana* and *tryphena*, whilst the *valeria* of the more westerly islands of Borneo, Sumatra and Nias and from Malacca show a scaleless subcostal vein. In the South Indian *pingasa* and especially in *octaviae* on the other hand the massing of the scales is still more distinct. The yellow ♀♀ of *leona* differ from East Javan yellow ♀♀ in having the circumcellular spots also intensively yellow, whilst in East Javan examples they always remain white. Also in *leona* the discal area of the hindwing beneath is characterised by a more prominent yellow. Such differences are indeed trivial, but make the study of the Javan fauna doubly interesting to the careful observer. We may add that the underside of the hindwing in *leona* is still more richly tinged with yellow than even that of *lutescens* from Borneo, Sumatra and Malacca. Moreover, on the median veins and the cell-wall beneath the black massing of scales is absent in *leona*, which *valeria* shows. Together with yellow ♀♀ there also occur in Java some with the upper surface uniform grey, which on account of their resemblance to *Radena juventa Cr.* may be designated forma **juventina** *nov.* Exclusively in East Java there is further a third, very rare ♀-form with the transcellular bars of the forewing entirely suffused with yellow as in *niasica* (**aureivena** *form. nov.*). ♀♀ of this description are a splendid mimic of *Danais philomela F.* — **baweanica** *Fruhst.* bears in the ♂♂ a very narrow black distal border to both wings: in the ♀♀, which are much lighter than even those of *leona*, the white-grey transverse bands are almost twice as broad as in Javan examples. Bawean. — **kangeana** *Fruhst.*, on the contrary, has a strikingly broad black distal border in the ♂♂, which are also noteworthy beneath for the broadly brown-grey veins. ♀ darker than that of *baweanica*. Kangean. — **sundana** *Fruhst.* (67 c) in the ♂ recalls East Javan *valeria* in the broad covering of scales at the subcostal of the hindwing beneath, but is distinguished from all known races by the almost black ♀♀, which bear only narrow white interneural streaks. Not rare in Lombok, and ascending from the coast to the plateau of Sambalun at 4000 ft. April—June. — **sumbawana** *Fruhst.* (66 ♂, ♀ called by oversight *austrosundana*). Bali (?). — **tryphena** *Fruhst.* Like almost all the Sumba butterflies (with the exception of *Pap. merapu Doherty*) smaller than its nearest allies from Sumbawa and Java. The black distal border of both wings is considerably narrower and also the black scent-patches on the underside of the hindwing much reduced. I do not possess the ♀; it probably differs even more from Sumbawa-♀♀ than the ♂♂. Sumba, Flores, perhaps also on Timor. On the islands of Kalao and Tana-Djampea, to the north of Flores, *valeria* is wanting. It is there replaced by an offshoot of the Celebes *triaea Fldr.* But there still remains one interesting *valeria*-race to record. — **palavana** *Fruhst.* (66 d), distinguished by the light colour of the upper surface, the very narrow black distal border, the strong, almost quadrate submarginal spots of the hindwing. There occurs also a somewhat darker form of the ♀ than the one figured. Common in January—February on Palawan. — **gulussa** *subsp. nov.* is a race with still further reduced black distal border, without a trace of white submarginal dots on the forewing, which is strongly rounded. ♀ similar to *juventina* from Java, but darker than *palawana*. Island of Cuyo. — **calliparga** *subsp. nov.* is the name of a form which approaches *lutescens Btlr.* from Borneo in the more extended, darker, yellowish tinge of the hindwing beneath, but differs from it in the more pointed wings and the brownish yellow under surface of the hindwing in the ♀♀. Islands of Domoran and Paragua.

leona. *juventina.* *aureivena.* *baweanica.* *kangeana.* *sundana.* *sumbawana.* *tryphena.* *palavana.* *gulussa.* *calliparga.*

P. pingasa, whose larva lives on Capparis heyneana, is characterised by the broad black distal border of both wings, which on the hindwing is provided with a slightly glossy layer of densely placed scent-scales. Larva long, cylindrical, with large head, abdomen terminating in two points, body covered with fine hairs, ground-colour green with a lateral row of conspicuous white spots and some smaller black dots. Pupa fastened by the tail and an unusually long thread, wing-cases strongly projecting, keeled and so thin as to be transparent. Ground-colour pale watery green (AITKEN). Three well differentiated local races belong here. — **pingasa** *Moore* (66 e), whose ♀♀ approximate to large ♀♀ of *hippia*. South India to Kanara and Mysore. — **ceylanica** *Fldr.* (66 e), founded on a rainy-season form, of which **fraterna** *Moore* (66 d) [1]) is the dry-season form, whose ♀ is much more broadly striped with blue-green, **spiculifera** *Moore* being an intermediate form. Ceylon. — The ♀ of **naraka** *Moore* has the grey-white transverse bands somewhat broader than *pingasa*-♀. Otherwise the under surface with its broadly black veins more nearly approaches South Indian specimens than *ceylanica*-♂♀, which have a bright mother-of-pearl sheen on a ground which is minutely dusted with brown-black. Andamans. — The specific distinctness of *pingasa*, as

pingasa. *ceylanica.* *fraterna.* *spiculifera.* *naraka.*

[1]) According to SWINHOE *fraterna* also occurs in exactly the same form in South India. SWINHOE regards it as a distinct species; it is, however, not impossible that *fraterna* is a highly specialised subspecies of *valeria*. NICÉVILLE on the other hand refers all three forms to one species.

already mentioned, is somewhat doubtful, but the genitalia show rather important differences. The uncus of *pingasa* is straighter and distally less curved than that of the *valeria* series of forms, the valve much broader, more rounded and distally less pointed.

P. boebera. A species of somewhat doubtful validity, parallel to *pingasa* in the broad scent-patch of the hindwing, but on the other hand in the very variable ♀♀ so closely allied to *valeria* that it may perhaps be regarded as only its most northerly branch. But as the forms of *boebera* form a natural group, they may here be provisionally treated as belonging to a collective species. Like the continental *hippia* and *persides boebera* varies on the Philippines both according to the locality and the season, the latter, on account of the greater climatic variations, more on the northern than on the southern islands. All the ♀♀ of the dry cold season are entirely white-spotted, those of the rainy season somewhat yellow with more extended black markings. Transitional forms have a bluish white sheen. As we go from north to south the black distal border of the ♂♂ increases in width, so that the *boebera*-♂♂ of the South Philippines approximate to those of *phocaea* (66 e) and according to SEMPER it is even difficult to separate the ♀♀ of the two species. **boebera** *Eschsch.*, of which we figure the ♂ and ♀ of the rainy-season form (**phazania** *form. nov.*) (66 c), has both sexes of the dry-season form essentially smaller, with larger white subapical spots on both wings, the ♂ lighter blue, the ♀ dull green-white. Luzon. — **hemara** *form. nov.*, found in North-West Luzon at Vigan, is an intermediate form, which SEMPER figured (Schmett. Philipp. pl. 42 fig. 7) and which differs from the cold-season brood in having the bands narrower and yellowish instead of whitish. — **arsamota** *subsp. nov.* is smaller than even the winter form of *boebera* and is beneath only slightly suffused with blue-grey with very long but narrow transcellular stripes on the hindwing. Island of Negros. — **bazilana** *Fruhst.* approaches *pingasa Moore* from South India in the broadened black margins of both wings. The ♂♂ are suffused with dark green instead of light blue, the forewing bears either no spots at all or only one subapical white patch. The ♀♀ beneath blue-black almost to the middle of the wing. Three forms of the ♀ are united in the FRUHSTORFER collection, that of the rainy season together with a transitional form with blue-violet sheen on both wings (f. **lilacina** *form. nov.*) and an apparently extreme dry-season form, recalling *hemara* from Luzon and *persides*-♀ from Annam, with reduced white-grey transverse stripes on both wings, which are densely dusted over with black (f. **persidina** *nov.*). Bazilan, near Mindanao. — **elaitia** *subsp. nov.*, the darkest of all the known races, distal border of the hindwing extended to the middle cell, subapical spots of the forewing entirely absent. Island of Panaon.

boebera. phazania. *hemara.* *arsamota.* *bazilana.* *lilacina.* *persidina.* *elaitia.*

P. tritaea is the largest species; its origin is perhaps to be traced to Mindanao, at the head of the ancient bridge of land connecting the Philippines with Celebes, unless conversely it was rather its representative *phoeaea* which came from Celebes to the zoologically allied Mindanao. On Celebes itself the species is split up into two essentially modified subspecies, of which **tritaea** *Fldr.* (67 a) is characteristic of the edges of the woods in Northern Celebes. In Central Celebes and in Gorontalo at the eastern arm of the island flies in the months of August and September a smaller dry-season form with somewhat purer and larger white streaks and spots and lighter grey-brown tinge on the under surface of the ♀♀ (f. **caecinia** *form. nov.*). In Southern Celebes not only the pattern is different but also the shape, especially the forewing being more rounded, in the ♀♀ the brown-violet tinge on the upperside of both wings is absent, and the submarginal spots are almost twice as broad, being particularly prominent on the underside of the hindwing in the shape of beautiful, white star-shaped patches. We name the South Celebes race **bargylia** *subsp. nov.* Common at the waterfall of Maros. — On Bangkai occurs a similar, still smaller race, **hermocinia** *subsp. nov.*, with darkened stripes in the cell of the forewing, reduced submarginal dots and obsolete circumcellular spots on the hindwing. — **bilinearis** *subsp. nov.*, in size a transition from *tritaea* to the next island form, differs from both in having the black stripes of the cell prolonged to the base of the forewing, being hence almost as long again as in *tritaea*, whilst in *oetaviae* they are absent. Hindwing almost without basal, i. e. much abbreviated blue-green longitudinal stripes inside the cell. Salayer, discovered by Dr. MARTIN. — **octaviae** *Snell.* (67 b) has ♂♂ with or without short black stripes before the apex of the cell of the forewing. The ground-colour lighter blue than in *tritaea*, ♀ approaching that of *bargylia Fruhst.* from South Celebes, with lighter transverse bands and shorter black lines in the cell of the hindwing. Under surface of the ♂♂ without a trace of black tinge, brilliant blue-white and with a strong mother-of-pearl gloss. Subapical stripes of the ♀♀ on the underside of the forewing essentially broader than in the Celebes *tritaea*-races, hindwing margined with lighter brown. Common on Tana-Djampea and Kalao, especially in December.

tritaea. *caecinia.* *bargylia.* *hermocinia.* *bilinearis.* *octaviae.*

P. phocaea *Fldr.* from the South Philippine region must perhaps be regarded as a subspecies of the gigantic *tritaea Fldr.* from Celebes, a question, however, which can only be decided with the help of larger series, especially of ♀♀. The genitalia, for instance, are somewhat different, the uncus of *phocaea* decidedly shorter than that of *tritaea Fldr.* *phoeaea* is very constant according to SEMPER, who was able to examine almost 900 specimens. The ♀♀ always bear in the cell of the hindwing above a black longitudinal streak, which is but rarely present in the *boebera* and *valeria* races. The strongly convex costal

margin of the forewing proves its relationship to *tritaea*, from which it only differs essentially in the darker smoke-brown under surface, particularly of the hindwing. — Two island races may be mentioned: **phocaea** *Fldr.* (66 e), known from the whole of Mindanao, and **ariamena** *subsp. nov.*, usually a third smaller, with still more reduced greenish blue strigae on both wings, of darker blue colour and with somewhat lighter brown under surface. Bazilan. *phocaea.* *ariamena.*

P. argolis combines the character of two species, the colouring of the upper surface appears to be borrowed from *phocaea* from the Philippines, that of the under surface from the Papuan *jobaea*. The ♀♀ in their general appearance more recall *jobaea*, but their upper surface shows also points in common with *valeria Cr.* — Two local forms: **argolis** *Fldr.*, from Batjan and Halmaheira. ♂: hindwing beneath black with inconspicuous thin green stripes in the cell and obsolete dots of the same colour before the distal margin. The ♀ appears in the form figured (67 a), which was already known to Snellen Van Vollenhoven and which is a close mimic of the yellow *Danais cleona*. But a grey form is commoner, recalling *Radena sobrina* from the Northern Moluccas (f. **radenoides** *form. nov.*). — I have before me from Buru an apparently very rare subspecies, **argolina** *Fruhst.* On the underside of the hindwing there are 2 costal, greenish longitudinal bands, which in *argolis* are entirely absent. The whole cell is whitish green and there are 5 large circumcellular spots, which in *argolis* from Batjan are likwise absent and in *argolis* from Halmaheira are scarcely indicated. Instead of very small dots *argolina* has a row of 6 distinct submarginal spots. *argolis.* *radenoides.* *argolina.*

P. jobaea *Bvd.* differs from *phocaea*, *tritaea* and *argolis* in the absence of black stripes on the upperside of the wings, but especially in the still shorter, though very broad scent-area of the hindwing, which does not extend beyond the radials. The costal margin and apex of the forewing as well as the surface of the hindwing beneath are deep velvety black throughout. — A series of insular races deserves mention: **elsa** *Fruhst.*, from Ceram, differs from *jobaea* from New Guinea in its small size and in the somewhat narrower black distal border of the wings. The uppermost whitish green spot of the forewing beyond the cell is longer and broader than in *jobaea*. On the underside of the hindwing is placed a row of 6 pure white, rather large, prominent submarginal dots. Vollenhoven figures a form of the ♀ with pale ochre-yellow upper surface, which bears on the forewing a light lemon-yellow stripe above the submedian and in which also the submarginal dots of the hindwing appear light yellow beside some white circumcellular patches. — **aeboja** *Fruhst.*, rare on Buru, is even smaller than *elsa*-♂ from Ceram, with the forewing only 32 mm long, and the black distal border of the wings is considerably narrower. On the upper surface of the forewing there are distinct, elongate, green subapical streaks, which break up the green-black distal border, and on the underside of the hindwing we find instead of the dots likewise 5 thin greenish submarginal interneural streaks. — **obiana** *Fruhst.* (67 b) is known by the rounded shape of the wings in both sexes. ♂♂ not rare on Obi, of the ♀ as yet only the yellow form similar to *Danais cleona* is known. — **luceria** *Fruhst.* (67 c) approaches true *jobaea* in its size; together with the yellow ♀ figured occurs also a form with grey-green bands above, which, however, on account of its relatively narrow transverse bands is not closely approximated to the Danaid model from Waigeu (*Radena purpurata Btlr.*). — **jobaea** *Bdv.* (67 b) is apparently rare in New Guinea, only known from North-West Dutch New Guinea, and does not extend beyond Humboldt Bay, since there is no record of its occurrence in Kaiser Wilhelm's Land. — **aviena** *subsp. nov.*, without exact locality, possibly from the Key or Aru Islands, differs from the preceding in a row of strikingly large white submarginal spots on the hindwing beneath. The subapical streaks of the forewing beneath very pronounced. The black distal border of the forewing above is somewhat narrower, so that the blue band beyond the cell is broader. — The early stages of the collective species are unfortunately not yet known and of the imagines we only know that they occur everywhere on the Southern Moluccas and that their flight is so rapid that they are difficult to catch. *elsa.* *aeboja.* *obiana.* *luceria.* *jobaea.* *aviena.*

27. Genus: **Saletara** *Dist.* [1])

This genus, which is defined by its facies, only differs essentially from *Appias* in the neuration in that subcostals 3 and 4 arise quite near the apex of the forewing and that subcostal 4 is always absent in the ♀♀ of the Malayan species and in all the species of the Papuan region and is mostly wanting in the Philippine races. The ♂♂ are also characterised by a long tuft of hairs on the last abdominal tergite above the anal claspers and by the two ventral hair-pencils being also composed of longer hairs than in *Appias*. The genus is however not yet very stable, and the tendency of the Pierids to drop some of the veins is here so much in evidence that sometimes examples are met with in which the right wing has the normal number of veins and the left wing one more or one less. The species exclusively inhabit the plains and are found without exception at wet places on the banks of rivers or at puddles in the woods. The flight is swift and steady. The early stages are not known.

[1]) This and the following genus should have been placed after *Appias*, but have been inserted here by mistake.

S. panda, distributed from the Philippines to Celebes, Sumatra and the Nicobars, occurs especially
nivaria. in the Macromalayan district almost always in 2 male and 2 female colour-aberrations, one pale whitish
sulphurea. (f. **nivaria**) and one sulphur- to lemon-yellow (**sulphurea** *Voll.*). — **nathalia** *Fldr.* is the most northerly race
nathalia. of *panda*; ♂ whitish yellow, ♀ with black distal border and black submarginal band on the forewing
martia. beneath, which is only indicated on the underside of the hindwing. Luzon. — **martia** *subsp. nov.* (61 f, 3) has in the ♂ a broader black margin to the forewing, in the ♀♀ the basal area of the hindwing is also tinged with black and the hindwing bears on the under surface an extended submarginal band on a yellowish green ground. Two forms, one with sulphur-yellow and another with hyaline blue-white central
erebina. areas on both wings. Bazilan, Mindanao. — **erebina** *Fruhst.* (61 f ♂, the ♀ belongs to *martia*), from Palawan, has three ♀-forms: central area of both wings light sulphur-yellow, or with light yellow forewing and lemon-yellow hindwing, or with the upper surface of the wings lemon-yellow throughout. All three fly in
hostilia. January. — **hostilia** *subsp. nov.* is larger, darker yellow, the distal margin of the hindwing more deeply dentate proximally, under surface of the forewing more greenish yellow, submarginal band of the fore-
nigerrima. wing narrower than in *erebina*. Balabac. — **nigerrima** *Holl.* (62 a) inhabits Celebes; the almost entirely black ♀ resembles the ♀ of *Appias urania Wall.* above, but has the whitish yellow central areas of the forewing somewhat more extended. Contrary to the general rule, the under surface of the forewing is white with the exception of the cell and the apical area; ♀ with very broad black subapical band on the forewing, cell of the forewing suffused with greenish yellow, hindwing without markings, dark ochre-yellow. Hitherto only known from Southern Celebes, from the waterfall of Maros, where it occurs from August to
aurantiaca. January. — **aurantiaca** *Stgr.*, from the Sula Islands, has the hindwing brilliant fiery red-yellow. The forewing resembles that of *chrysea*, but the black distal border is more finely divided and runs further into the
panda. cell along the veins. — **panda** *Godt.* (61 f) is the name-type of the species, from Java, where besides the
nivaria. dark yellow examples figured pale yellow specimens of both sexes also frequently occur (f. **nivaria**). The butterflies were not rare in East Java at certain times, particularly in January—February, but do not ascend above 2000 ft. I doubt the correctness of the locality of examples from Sumba and Sumbawa in
balina. my collection. — **balina** *Fruhst.*, which is essentially smaller, has the black margins on the upper surface
distanti. much narrowed and the subapical band on the forewing beneath obsolete. Bali. — **distanti** *Btlr.*, from the Malay Peninsula and probably occurring in very similar forms also on Sumatra and Borneo, has light yellow wings, ♀ on the forewing with a deeper black border, on the hindwing with a narrower one, than
schoenbergi. Javan ♀♀. — **schoenbergi** *Semp.* (61 f), with canary-yellow ground-colour and pale yellow costal margin to
engania. the forewing, has the ♀♀ sometimes lemon-yellow, sometimes light ochre-yellow. Nias. — **engania** *Fruhst.* (62 a) has the ground-colour of the delicate cream-colour above only, the under surface of both wings being
aurifolia. as brightly and uniformly orange as in *schoenbergi*. ♀ unknown. Engano. — **aurifolia** *Fruhst.* (62 a). Forewing light, hindwing darker orange-yellow, forewing with uniform, narrow black submarginal band, which
chrysea. is only distally slightly tinged with violet. Island of Pulo-Tello in the Batu Group. — **chrysea** *Fruhst.* approaches *schoenbergi*, but has a proximally more uniform and more sharply defined distal border to the forewing, which is light yellow apically. Under surface fiery orange-yellow. ♀ similar to that of *aurifolia*, but with the black border almost twice as broad. Nicobars.

S. liberia replaces *panda* on the Moluccas; but the yellow ground-colour of the upper surface is changed to grey-blue, only the yellowish under surface reveals the relationship. — The typical subspecies
liberia. **liberia** *Cr.* (62 b), from the Southern Moluccas, has the under surface of the forewing light yellow-green and the hindwing dark orange-colour, The ♀ is very rare and has the veins less broadly black than
eliada. **eliada** *Hew.* from the Northern Moluccas, which in its turn approaches **obina** *subsp. nov.* (62 a, b). In the
obina. latter, however, the black distal border is always broader, especially on the underside of the forewing. The
principalis. ♀♀ are polychromatic; they are as follows: f. **principalis** with the black distal border broken up and proximally running out in streaks. Under surface: both wings distally only spotted with black in parts. Base of the forewing greenish yellow; apex and hindwing ochre-yellow; forewing with a diffuse submarginal band
vada. which does not reach the costal margin. f. **vada;** distal margin of both wings broadly black, compact. Under surface: both wings greenish yellow with a somewhat more distinct submarginal band on both wings.
pseudo-corinna. **pseudocorinna** *form. nov.*; upper surface either blue-grey as in the preceding or almost white-grey as in *corinna Wall.*-♀. Black distal margin on both wings above and beneath compact, very broad. Under surface: base of the forewing greenish, central area whitish; surface of the hindwing above either light or
chryso-berylla. dark ochre-yellow. — **chrysoberylla** *subsp. nov.*, above darker blue-grey than *liberia*, with broader black distal border. Under surface of the forewing lighter grey and the apex of the forewing as well as the surface of the hindwing light greenish yellow instead of orange-coloured as in *liberia*. Buru, common.

eyeinna. **S. cycinna** *Hew.* (62 a, b) inhabits the Papuan region, from which only three island races are yet known. The typical subspecies was described from New Guinea. Dutch and British New Guinea. — The
ocina. ♀-form figured as *cycinna* was described by Hewitson as a separate species under the name **ocina.** The forewing is white also beneath with light yellow tinge in the cell, the hindwing dark canary-yellow. Its habitat is pretty certainly not New Guinea. — On the Aru Islands occurs a hitherto undescribed race:

chryselectra *subsp. nov.*, which differs from *cycinna* above in the lighter, more purple-blue colour. Under- *chryselectra.*
side of the forewing pure white, not grey-blue, cell suffused with saffron-yellow, distal border twice as broadly black, more sharply defined. Hindwing brilliant orange-coloured instead of yellow-green. Of the ♀ there are 2 forms, one above white and the other, which is rarer, yellow (**flavescens** *Ribbe*). — **corinna** *flavescens. corinna.*
Wall. is a distinct local form from Waigeu, with the hindwing similar to *cycinna*, only somewhat darker orange on the under surface. ♀ white, beneath with deep black, broader, distal border. Forewing beneath white, with the cell dusted over with greenish. Hindwing with dark yellow basal area, which in ♀-form **hastia** *form. nov.*, from Kayumera Bay, Dutch New Guinea, is light lemon-yellow and the upper surface *hastia.*
of the wings is darker scaled.

S. giscon *Gr.-Sm.*, a species from the Solomon Islands which is unknown to me in nature, is said *giscon.*
to be similar above to the ♀ of *panda* from Java.

28. Genus: **Udaiana** *Dist.*

This genus forms a transition from *Appias* to *Huphina* in the absence of the ventral tufts of hair in the ♂♂, but differs from both in the position of the second subcostal vein, which as in *Parelodina* arises quite near the apex of the cell of the forewing. Only one species is known, which inhabits Macromalayana with the exception of Java and only occurs in the plains. The ♂♂ occasionally settle on moist places in the forset-paths, the ♀♀ were observed on a green climbing plant. According to Martin they are found in Sumatra only in woods where the soil is red, never in those where it is black.

U. cynis *Hew.* (62 c). The under surface is likewise white, the apex of the forewing dusted with *cynis.*
greenish yellow, costal margin of the hindwing bordered with yellow, base with some green scales. A very light ♀-form, which in its extreme has scarcely darker margins than the ♂, Hagen has named **androides.** *androides.*
Malay Peninsula, North-East and West Sumatra. — **pryeri** *Dist.* (62 c) is a darker local form from Borneo, *pryeri.*
characterised by the more deeply incised black distal border of the forewing and by the basal area of the hindwing beneath being always broadly scaled with green. North Borneo, rather rare.

Additions and Corrections.

P. 125: **D. hyparete aurago** *Snellen*, described from Billiton in the Tijdschr. o. Entom. 33, p. 303, *aurago.*
bears gold-yellow submarginal patches on the hindwing beneath and hence approaches *hypopelia Hag.* and *jataka Fruhst.*

P. 126: **D. agostina orita** *subsp. nov.* Forms a transition from *annamitica Fruhst.* to *infumata Fruhst.* *orita.*
and differs from the Annam race in the darker upper surface of the forewing, which is somewhat lighter than in *infumata* and bears much smaller white submarginal spots than in *annamitica*, hindwing as in *annamitica*, only somewhat more densely dusted with grey. Locality Tonkin; apparently very local and rare, as I did not myself observe it.

P. 130: **D.** *diva R. & J.*, preoccupied by diva *Fruhst.* 1899, must be replaced by **sagessa** *nom. nov.* *sagessa.*

P. 132: **D. belladonna formosana** *Mats.*, described in the Ent. Zeitschrift Stuttgart 1909, p. 92, *formosana.*
approaches *lativitta Leech* in the markings, but differs from it in that the white distal spots of the forewing are not united with the proximal ones and the hindwing above is almost entirely whitish at the inner margin, with light anal yellow dusting. All the spots small, but distinct. Formosa, Horisha.

P. 140: Line 12 from above read **ajanta** instead of *ajuta.* *ajanta.*

P. 142: Under *Huphina nadina eunama Fruhst.* an intermediate form should be mentioned, **koan-** *koannania.*
nania *Mats.* (Ent. Zeitschr. Stuttg. 1909, p. 88), with grey instead of green-yellow under surface. Kanschirei and Horisha on Formosa.

P. 149: Under *Appias lyncida formosana Wall.* Matsumura has described a ♀-form as **tsurui,** *tsurui.*
which according to the description belongs to a dry-season form and was collected on December 1 at the east coast of Formosa. — **yayeyamana** *Mats.*, from the Loo Choo Islands, appears to be a local race of *yayeya-mana.*
lyncida and was described from a ♂ with an expanse of 5—9 mm. (should probably read 50—60 mm).

P. 166: **Terias libythea punctatissima** *Mats.* is somewhat larger than the Malayan forms of the *punctatissima.*
species, ♀ very pale, and occurring according to my examples in two phases, either with narrow black margin to the hindwing above or with this more extended, reaching the anal angle. Formosa.

P. 182: Under *Saletara panda* Matsumura mentions a form **kawakamii,** from Katosho, an island *kawakamii.*
close to Formosa, with lemon-yellow ♀, which is said to be spotted like *nathalia.* A very interesting discovery, unless the form is a ♀ of *Appias albina.*

3. Family: **Danaidae.**

By far the most of the species of this purely tropical family belong to the Indo-Australian Region and only a few reach the temperate districts of Asia. Three genera occur only in the Indo-Malayan subregion, and only the genus *Danaida* has found its way also to Africa and America. The few non-Asiatic representatives of the genus *Euploea*, it is true, inhabit some East African outlying islands, which are perhaps remains of the old Lemurian bridge, but nowhere cross over onto the mainland.

In contrast to all the other families of butterflies the Danaids are poor both in genera and species and their forms moreover show a very uniform stamp. They are only to a small extent subject to seasonal influences, especially compared with the Pierids, and a proportionately large number of species are distributed over large districts without varying locally. These conditions are only changed in those Danaids which inhabit the Archipelagos, where, though being still less inclined to form species than the Pierids, they nevertheless produce a series of sharply separated races, which in the last century were regarded as good species. Naturally the few inhabitants of the Oceanian islands have altered most; those on the islands lying off the continent less so, although occasionally on these the formation of species appears to have proceeded *per saltum*. Vulcan Island, which is scarcely 12 km. from New Guinea, already produces a species which has not so far been found either on the main island of New Guinea or in its immediate neighbourhood. By far the largest proportion of the Danaids inhabit the plains; quite a number even do not ascend above the woods of the coast and in North Celebes I observed a Danaid flying high over the sea to the neighbouring islets. Only a few species inhabit exclusively alpine regions, and even these only quite exceptionally ascend above 2500 m.

The Danaids probably belong to an old Rhopalocera-stirps, whose primitive pattern almost always follows the veins on the wings or shows remains of the ancestral stripes, and which is repeated in nearly all the other Nymphalid families and even in Pierids and Papilionids, on which account the Danaids are often regarded as models for convergent or mimetic species.

Another indication of the great age of the Danaids is the filiform shape of the antennae, which recall those of the ancestors of Lepidoptera (Protolepidoptera) and the primitive form of the genitalia, which are the most uniformly developed of all the known butterflies. On the other hand, the Danaid males are provided with the most complete secondary sexual organs, which rank among the most interesting physiological phenomena of the insect world. Besides the patches of modified scales along the inner veins of the hindwing many species possess also sack-like pouches, which are filled with androconia and only exist in the Danaids, and also moveable anal hair-pencils, which are looked upon as scent-organs.

The hair-pencils of the Danaids consist of two parts, a tubular stylus and a rosette of radiating hairs of several mm. in length. The rosette of hairs is as a rule concealed in the stylus. In some species a light pressure is sufficient to project it from the tube. In *plexippus* the flexibility of the anal pencil appears to depend on the time of year and perhaps also on the nature of the food which the butterfly is taking.

The scent-organs of the Danaids consist of elongated sacs, surrounded by a flexible chitinous membrane, and placed on each side on the abdomen from the seventh to the middle of the fourth abdominal segment. Between them lies the muscular penis, which is surrounded by chitin. The scent-organs lie free in the body, only quite lightly fastened by fine muscles, and as they are not separated by any partition from the abdomen, they are probably directly nourished by the blood and projected by the pressure of the blood (Illig). In my experience the colour of the fluid ejected by the anal pencil varies, apparently according to the food which the butterfly takes, for in some examples of the same species the stylus was green, in others again dark straw-colour. Danaids discharge a globular secretion through the anal scent-hairs, but Euploeids octahedral crystals, which in the basal part are of larger, distally of smaller size. The scent-patches appear as folds, whose opening is turned away from the vein. The interspace between the fold and vein is filled with live cells.

Haase and others believe that the anal pencils play a part in copulation as organs of attraction. But according to my observations in Hong-Kong these organs, which look so delicate, seem rather to serve as weapons of defense or for frightening the enemy, for whether Euploeids were attacked by the wings or by the thorax, in every case they projected their anal pencil, moving it in the same way as wasps do their sting. The ejection of the hair-pencil is accompanied by the exhalation of a penetrating scent, smelling of honey. The scent-pencils of the Danaids are shorter than those of the Euploeids.

Nicéville once saw that *Euploea core* when flying about in the bright sunshine bent the abdomen forwards to the thorax and in doing so projected the scent-pencils.

The fearlessness of the Danaids is pretty certainly the result of the immunity which they enjoy in consequence of their acrid juices, which protect them against the attacks of birds and reptiles. At the same time their body is hard and leathery and experiments with spiders and fowls have proved that these insects are never acceptable to them as food. In my experiments on Lombok, if ever a hen seized upon a *Danaida* or *Euploea* by mistake, the butterflies were immediately thrown away again, and the beak even carefully wiped with evident signs of displeasure, in order to remove as quickly as possible the offensive smell or taste which the body had left behind.

The egg of Danaids is large, soft, shaped like a cartridge (according to MOORE like a sugar-loaf), more than half as high as broad, yellowish, sometimes pearly. All are strongly ribbed longitudinally with delicate horizontal lines, which vary in number and development and are difficult to count. The number of the longitudinal ribs differs also slightly even in the same species. The eggs of *Hestia* show a more hexagonal reticulation and the ribs run in zigzag, and the egg agrees on the whole more with that of the Euploeids (which we find repeated in the arrangement of spines in the larvae).

DOHERTY also considered it worthy of note that the transverse lines in the Danaids *s. str.* are usually more numerous than the ribs, whilst in the Hestias and Euploeids they occur more sparsely.

Respecting the larvae of the Danaids the reader is referred to the description in vol. I, p. 75: as food-plants various Asclepiadeae are preferred; often the butterflies are even limited by these in their distribution.

The pupae are suspended, short, smooth, oval, constricted in the middle and commonly ornamented with brilliant gold and silver gloss; they are often traversed by brown stripes, which in purely metallic pupae can also be artificially produced if the pupae are kept in the dark.

As principal characters of the imagines may be mentioned: Delicate and weakly clubbed antennae, large eyes and club-shaped abdomen and the peculiarly reduced, thickened and spinous forelegs in the female. They are easily distinguished from the Nymphalids and Satyrids by the submedian of the forewing being furcate at the base and from the few superficially similar Pierids by the reduced forelegs.

Tufts of white scales on the head and thorax, which are present even in otherwise entirely black individuals, are also characteristic of the Danaids.

The wings are mostly elongated, bag-shaped, rarely rounded; in the Euploeids differing in the sexes, but never pointed, as in Pierids or Papilionids. Tails are entirely absent, as in Pierids.

The cells of both wings are closed, but that of the forewing proximally provided with two points, which probably represent rudiments of veins, and which are scarcely ever found in the Nymphalids, but appear in many Satyrids. The clasping organs of the Danaids are remarkable for the aborted uncus and the unusually broad valve. The distal shape of the valve varies in *Hestia* from one local race to another, is in *Danaida sensu stricto* very diversified, but in the Euploeids extraordinarily constant, so that in the latter it cannot be employed as an aid in the determination of species.

All the Danaids are extraordinarily tenacious of life, and in Lombok or Siam examples often flew away when I opened a paper after many days. They have also a long season of flight and one brood follows another continuously. They but rarely frequent wet places on the road, showing a preference for the smell of dried wood, and are hence occasionally found in the verandas of houses, and MARTIN observed them under covered bridges in Sumatra. All the Danaids are gregarious and their abundance is sometimes astonishing. On Ceylon and Lombok I sometimes saw thousands in neglected village gardens overgrown with flowering weeds.

Euploeids also sometimes take part in the migratory flights of Pierids. They are given to flying long distances, sailing one behind another, apparently without purpose. All the Danaids are attracted by flowering trees, round which they gambol in hundreds.

The figures on pl. 74—86 have been drawn without exception from examples in the FRUHSTORFER collection, Genf Florissant, in which are also contained the types of the new forms described here.

1. Genus: **Danaida** *Latr.*

(*Danaida Latr.* 1805, *Danaus Latr.* 1809, *Danais Godt.* 1819.)

The species of this genus are distributed over the whole of the Indo-Australian Region, but decrease rapidly beyond the Tropics, only a few species reaching the extreme limit of the region; these naturally belong to the commonest representatives of the genus and in some cases even follow the spread of their food-plants by human agency. One species (*archippus*) has been quite recently transported from North America over the Pacific Ocean by means of shipping and is constantly advancing further towards the west both on the continent and the islands.

Almost all the species have a slow, clumsy flight, prefer open grass-plots, even village gardens and localities in large towns, such as Bangkok and Hongkong, and in contrast to the Euploeas and Hestias avoid dense woods

On account of their abundance they are among the most characteristic butterflies of the East.

Inhabitants of the plains (some forms scarcely ascending above the woods at the coast), only a few species are confined to the alpine region; in Java, however, *albata* ascends to 2500 m., and is not even afraid of the sulphureous vapour of the volcanoes.

All the Danaids keep near the ground and in my experience they but rarely visit trees, even when these are covered with flowers and attract whole swarms of Euploeas.

Next to the Euploeas, the species of *Danaida* are the most copiously provided with secondary sexual characters; a phenomenon which apparently runs parallel with the most varied development of the clasping organs. The uncus, however, is always feeble, of palpi-like shape, the tegumen provided with vermiform processes and the valve unusually broad, only rarely armed with spines, all the organs less chitinous than those of the Nymphalids and even the Satyrids.

The neuration, in contrast to the constancy of the Euploeas, varies within the groups, the first subcostal vein arising either before the end of the cell, exactly at it, or soon after. But these variations are not constant, changing even in representative species and sometimes within a species, and can only with caution be utilized as generic characters (as Moore has attempted to do). Middle discocellular of the hindwing either long and obliquely inwards (*Anosia*), or short and at right angles to the median (*Ravadeba*). Precostal of the hindwing arising at the point of origin of the subcostal. Antenna gradually thickened.

Egg large, the ends obtuse, with numerous longitudinal ribs, numbering according to the species 15 (*aglaioides*) to 34 (*hegesippus*), and prominent transverse lines, of which Doherty counted 22 (*melanoleuca*) to 38 (*tytia*). Larva smooth with variegated stripes or spots and fleshy appendages, of which the anterior flexible pair according to Seitz is used as a tactile organ. The number of these filaments varies from 2 to 3 pairs according to the group. The larva grows quickly and changes into a barrel-shaped pupa, whose anal part is sometimes shaped like a wasp's nest and hung up exactly like one.

Group Anosia *Hbn.* (1816).

Larva with two pairs of tentacles, without lateral stripes. Second subcostal vein arises at the end of the cell. Hindwing with a pouch of androconia sunk in at the third median vein.

D. archippus *F.* (= menippe *Hbn.*) (vol. I, p. 76 mentioned as *plexippus L.* and figured 28 c), originally a native of North America, where it flutters about even on the pavements of the large towns, has already been naturalized as an immigrant in Australia and East Asia — as it were a symbol of the American capacity for expansion. By the English *archippus* is called the „wanderer". It was first observed in 1863 on the Tonga Islands, in 1867 on Samoa, in 1871 in Queensland and in the same year on Celebes. It has reached Java and Penang and on Formosa is already one of the commonest species. In coll. Fruhstorfer it is also represented from the Fiji Islands, the Bismarck Archipelago, Dutch New Guinea, the Moluccas, Talaut and the Fergusson Islands. From Amboina I have before me an aberrant example with whitish yellow upper surface to both wings. According to the structure of the genitalia *archippus* is morphologically the most highly specialized form and may hence be regarded as one of the most recent branches of the Danaid stirps. Penis long, awl-shaped, slightly curved distally, very narrow, chitinous, not broadly soft-membranaceous as in the other *Danaida*. Uncus distinct, but likewise only slightly chitinized, basally broad, distally with strong obtuse point. Valve broad, somewhat recalling that of *Hestia*, with black-brown sharp distal point, ventrally slightly concave. *archippus.*

Group Limnas *Hbn.* (1806).

Second subcostal vein of the forewing arises at the apex of the cell, middle discocellular of the hindwing in the ♂ strongly elbowed, in the ♀ incurved. Androconia-pouch of the hindwing far removed from the lower median vein. Larva with 3 pairs of tentacles. Uncus aborted. Valve quadrate, distally with a scarcely perceptible point, but a long spine, which is directed ventrally with the point towards the last abdominal tergite.

D. chrysippus *L.* (vol. I, pl. 28 a, p. 75—76, where also larva and pupa are fully described). Egg shaped like a sugar-loaf, yellowish. Pupa sometimes green, sometimes wax-yellow, pupal stage 6—9 days. Larval stage lasts 12—14 days. This beautiful butterfly is one of the most widely distributed species in the world, its migrations already extending over four continents, while its immigration into the fifth is certain to follow sooner or later, whenever more direct steamboat communication is established between Africa and South America. The species is distributed from continental India to the Loo Choo Islands and eastwards from Nias to New Guinea. In continental India itself the species is common everywhere from *chrysippus.*

the plains up to 7000 ft. *chrysippus* is very variable both in size and in colouring and examples with white transverse bands on the forewing occur at the same time as those without band (*dorippus Klug*). Both ♂ and ♀ may have the hindwing yellow-brown throughout or sometimes entirely suffused with white. Hagen bred the latter form (*alcippoides Moore*) in Sumatra from a dozen larvae off a single plant together with
dorippus. true *chrysippus*. — The form **dorippus** *Klug* occurs in India only sporadically in the Punjab and Ceylon; but
bowringi. it has been repeatedly taken in Aden in copula with white-banded *chrysippus*. — As **bowringi** *Moore* a form from Hong-Kong has been described with larger white spots on the forewing than normal *chrysippus*,
clarippus. and as **clarippus** *Weym.* a conspicuous and rare aberration from Nias with white cell to the forewing and
vigeli. the oblique band twice the normal breadth. Hindwing beneath with white flame-like markings. — **vigeli** *Heyl.*, from Pulo Bras, an island off the north-west point of Sumatra, is distinguished by the reduction
bataviana. of the white spots and by the dark red-brown ground-colour. — **bataviana** *Moore* is a race from the Macromalayan region, which occurs in Java and the neighbouring islands as far as Lombok and also in western Sumatra, whilst in the north-east of Sumatra occurs only the lighter yellow continental Indian *chrysippus*, which has probably only recently immigrated and supplanted the darker endemic form. Ground-colour dark red-brown instead of honey-yellow, the black distal margin of the wings somewhat more regular, the white dot at the end of the cell of the forewing inclined to obsolescence. Occasionally the black apical area of the forewing bears a red-brown patch; in a ♂ from Batavia a whitish dusting is also noticeable beyond the white oblique band, and in ♂♂ from West Sumatra the *alcippoides*-pattern occurs, which contrasts vividly with the dark brown ground. There are also examples which bear 2—3 round white patches in the postdiscal area of the forewing beneath. The latter character occurs constantly in a charming form from Central Celebes in combination with white flame-like markings on the hindwing above
gelderi. and beneath = **gelderi** *Snell.* (77 e), probably an extreme dry-season form, occurring in August and September, especially near Donggala. Particularly noteworthy is a large oblong white spot, sometimes also with rose-coloured sheen, between the median and submedian of the forewing beneath. In southern Celebes and other parts of the island *gelderi* has not yet been observed. Here occurs again a normal *chrysippus*-form recalling *bataviana*, which I have also before me from the Talaut Islands. — In the
petilea. Micromalayan region *chrysippus* appears on almost every island in a light yellow (**petilea** *Stoll*) and a dark
cratippus. red-brown colour-aberration (**cratippus** *Fldr.*). It is, however, almost impossible to draw a line between *petilea* and *bataviana*, so much the more as transitional forms are found in Sumbawa and Sumba. But as principal characteristics of *petilea* may be cited the much widened black distal border of both wings and the absence of white dots on the hindwing above. Habitat of the name-type Amboina; occurring on all the Moluccan islands to North Australia, and in my collection from all the islands of the Timor Group. — Two forms extend into the Palearctic Region: *aegyptius Schreber*, a name which I would revive for examples from Palestine and Greece. Palestine specimens, with which Egyptian probably agree, may be distinguished from all other races of *chrysippus* by the fiery red-brown of the cell and the central area of the forewing, which becomes gradually darker towards the costal margin and occasionally extends also onto the cell of the hindwing. The distal area of the hindwing, however, always remains light yellow-red. The beautiful red-brown is repeated also on the underside of the forewing. Common in Palestine, in gardens at Cairo and Khartoom, rarer in the Soudan. — *kanariensis Fruhst.* is an island form, which approximates to *aegyptius* and apparently always has the abdomen entirely black above. Common on the Canary Islands.

Group Danaida *Latr.* (Salatura *Moore* 1883).

Neuration as in the preceding group, but the middle discocellular not angled in the ♂. Androconia-pouch likewise free. Larva with 3 pairs of tentacles, somewhat shorter than in *chrysippus*, valve without ventral point turned towards the tergite, but distally with a more or less snout-shaped projecting process, which only differs very slightly in the various species.

plexippus. **D. plexippus** *L.* (vol. I, p. 76, figured under the synonym *genutia Cr.*, pl. 28 c) is a collective species, which Linné first correctly described, but erroneously transferred its locality to America, where species with white oblique band on the forewing, which Linné expressly mentions, do not occur. The species is otherwise very similar to *chrysippus*, but easy to distinguish by the broadly black veins of the hindwing and a dark brown instead of yellow apical area on the forewing beneath. Larva and habits of the butterfly are described in detail vol. I, p. 76. Common in the whole of the Indo-Australian Region, the species extends northwards to Formosa and the Loo Choo Islands. Next to *Eupl. mulciber* it is one of the most repulsive-smelling Danaids and it is accepted that it serves as a model for a series of other butterflies, such as e. g. certain species of *Elymnias*. The scent-apparatus embedded in the hindwing of *plexippus* near the submedian is 1 mm. thick and fleshy, but almost tasteless on the tongue. The scent-scales surrounding it have a smell like carrion, which according to the notes in my diary surpasses that of all the species hitherto observed by me and smells like the burying-beetles. Moreover this smell is as penetrating after 36 hours as when the butterfly is first killed. The body still smells offensive even after the removal of the hindwing. In order to squeeze out the scent-pencil of examples of *plexippus*, with

which I experimented in Hong-Kong on the 29. Oct. 1899, a strong pressure was needed. Later I found in Annam and in January 1900 in Saigon that the species has the habit of extending the scent-pencil of its own accord without any outside stimulus, in contrast to *melanippus indicus Fruhst.* The stylus itself is filled with a yellowish or reddish fluid, whose colour naturally depends on the flower-juices on which the butterfly feeds. This has an acrid taste on the tongue. Valve broad, with the centre excurved in shape of a semicrescent and little projecting chitinous tip. Two aberrations deserve mention, a melanotic one: **nipalensis** *Moore*, hitherto only known from Nepal, with the white oblique band of the forewing much narrowed, and **grynion** *Fruhst.*, an albinotic dry-season form of light yellow instead of reddish yellow ground-colour and very small size. Black distal border of the hindwing very narrow. Under surface of the hindwing whitish. Apical area of the forewing light grey instead of red-brown. Known from Annam and Sikkim and taken in February—March. In addition the following geographical races are recorded: — **intermedia** *Moore*. As a rule as large as the finest *plexippus* from China and Siam, but the cell and the interneural spots of the hindwing above and beneath pure white. Occurs on the Malay Peninsula and in Singapore as the principal form, but in Siam (Angkor), Cochin China (Saigon) and Tonkin in the dry season as an aberration together with *plexippus typica.* — **sumatrana** *Moore* (77 c) is always smaller than *intermedia* with essentially narrower white oblique band on the forewing and still more extended and purer white interneural stripes on the hindwing. Common in West and North-East Sumatra. — **niasicus** *Fruhst.* is a very rare race, of which only a few examples have as yet been brought to Europe, very nearly allied to the Javan subspecies and differing from it principally in the broader black bordering of the wings and the still more thickly black veins of the hindwing. Nias. — BUTLER has described from there a form **leucogyne** of which I have not been able to decide whether it is an aberration of *chrysippus* or *plexippus.* — **intensa** *Moore*, of the colouring and size of *partita*, but with the white bands on the forewing almost twice as broad. In general darker than *plexippus* and with reduced white markings on both wings. *intensa* occurs on Java, Bali, Bawean and singularly also both Northern and Southern Borneo, without varying much. On Java it is one of the commonest butterflies and ascends to about 800 m. — **partita** *Fruhst.* (77 c) replaces *intensa* on Lombok and is a more melanotic form of the latter. The white subapical spots on the forewing are mostly even smaller than in the example figured and are then more isolated, also in almost all ♂♂ the small white streaks at the costal margin before the apex of the cell are absent, which are found in all the other races of *plexippus*, but appear again in ♂♂ and ♀♀ from Sumbawa, Lomblen and Alor. *partita* has been described from Lombok, where it is extremely common at about 6—700 m. in the village gardens, so that the natives sometimes brought me many hundreds in one morning. — **wetterensis** *Fruhst.*, which is smaller than *partita*, bears nevertheless a strikingly broad and pure white band on the forewing on a still darker red-brown ground. The dot-like white patch between the median veins of the forewing is very large and the distal border of the hindwing as in *plexippus* adorned with a distinct double row of small white dots. Veins of the hindwing beneath accompanied by distinctly prominent whitish streaks. Wetter, common. — **laratensis** *Btlr.* has more extended brilliantly white oblique bands and a very large spot between the medians on the forewing; it is also somewhat larger than *wetterensis* and traversed by less prominent white streaks beneath. Timor-Laut Islands. — **kyllene** *subsp. nov.* A transitional form between *wetterensis* and *partita*; smaller than all the island races mentioned and with a correspondingly narrower white subapical band on the forewing. The small streaks at the end of the cell, the interneural spot on the forewing and the marginal dots of the hindwing are somewhat reduced. On the under surface the white stripes on the veins also are only indistinct. According to KÜHN the form occurs all the year round on the Key Islands at open places overgrown with alang-alang grass. The name-type comes from Dammer, I have ♂♂ and ♀♀ in my collection from Kisser also. — **conspicua** *Btlr.* (77 c), from South Celebes, is essentially modified. The white spots of the forewing are of unequal length, the cell of the hindwing assumes an almost entirely white colour, in which but rarely finely scattered reddish scales recall the original *plexippus*-colouring. The under surface of the hindwing is also characterized by a submarginal row of more or less distinct white patches, which are wanting in other races of *plexippus*. *conspicua* is one of the commonest butterflies of southern Celebes, where it flies all the year round, even in the height of the rainy season, and ascends to above 1000 m. — **leucoglene** *Fldr.*, described from Minahassa, bears somewhat broader white bands on the forewing and mostly also on the upperside of the hindwing large and distinct lunular patches. Likewise from the coast-forests up to about 1000 m., one of the ornaments of the landscape. — **tychius** *subsp. nov.* is a smaller race with the white bands on the forewing much reduced, the white dots on the upperside of the hindwing very small and the whitish submarginal patches on the underside entirely absent. Habitat: the long island of Saleyer to the south of Celebes. — **telmissus** *subsp. nov.* Above very similar to *partita*, but with still narrower white subapical stripes on the forewing and very broad black margins to both wings, which are only beneath sparsely dotted with white. The cell of the hindwing also only recalls *conspicua* beneath, above it is dark red-brown even in the ♀ with the exception of an indistinct whitish tinge. Island of Buton, discovered by Dr. L. MARTIN. Finally, there is further a *plexippus*-race from Australia to be mentioned, which I have never seen in nature, but concerning which WATERHOUSE states in the Catalogue of Austral.

nipalensis. *grynion.* *intermedia.* *sumatrana.* *niasicus.* *leucogyne.* *intensa.* *partita.* *wetterensis.* *laratensis.* *kyllene.* *conspicua.* *leucoglene.* *tychius.* *telmissus.*

Lep. that an endemic form occurs in North-West Australia, of small size and nearly identical with *laratensis Btlr.* from Timor-Laut, whilst in Queensland there is a large race which approximates to the Chinese name-type and must be regarded as a recent introduction.

melanippus. **D. melanippus** occurs together with *plexippus* on the continent and on some islands of the Macromalayan region. It has always a darker coloured body than *plexippus*, and apparently cannot project its anal pencils of itself; it needs at least a very strong pressure to squeeze them out. *melanippus* appears to be a decadent species and to make up for its want of sexual activity by intensity of colouring, especially *indicus.* the Indian race. — **indicus** *Fruhst.* (77 c) with its largely white hindwing is a beautiful butterfly. It is much rarer than *plexippus*, especially at the extreme limit of its range, e. g. at Calcutta, which it only occasionally reaches, whilst in the whole of Further India from Tenasserim to Rangoon and Cochin China it always occurs in abundance, and in Saigon even forms an ornament of the botanical gardens. — Still *hegesippus.* more common is **hegesippus** *Cr.*, originally described from West Sumatra, but also occurring on Singapore, the Lingga Archipelago, the Natuna Islands and the Malay Peninsula. SHELFORD has recently shown that it also occurs in West Borneo. It is somewhat smaller than *indicus* and constitutes a melanotic form of this with reduced white transverse bands on the forewing and broadly black veins on the hindwing, which, especially in Sumatran examples, bears beneath broad brown streaks in the basal area, whilst in *indicus* this part is pure and dazzling white. Valve very different from that of *plexippus*, more rectangular, distally strongly contracted with thin, narrow, beak-like apex. Whilst *melanippus indicus Fruhst.* scarcely varies on the continent from Burma and Tenasserim to Saigon, the species begins to lose its fixity as soon as it enters the maze of Malayan islands. A few sea miles of distance suffice there to change the races so much that their specific identity can only be ascertained with difficulty; in fact the separate island forms were regarded for decades as true species. Especially on the islands near Sumatra the capacity of the species for forming races is seen at its maximum. The otherwise constant ground-colour changes from red-brown (*pietersi* from Engano) to black-brown and black (*keteus, umbrosus, eurydice*). Two directions of variation may be recognized. The *pietersi*-branch, which gravitates towards Java, and a second (*eurydice*, etc.), which gravitates towards the Nicobars. The races of the two lines, apart from the influence exercised by the sea as a separating factor, might represent at the same time the relics of an ancient fauna. The red-brown *pietersi*, which we know from Engano, may derive its origin from the land-connection with Java, whilst the black-brown forms of the more northerly islands may be regarded as the *nesippus.* faunistic remnants of a tongue of land Mentawej-Nias-Nicobars. — **nesippus** *Fldr.*, from the Nicobars, has preserved in the cell of the hindwing and its immediate neighbourhood the white markings of *indicus* and *hegesippus*, especially on the under surface, where the red-brown submarginal patches are only a little more *umbrosus.* strongly developed than in the Sumatran name-type. — In **umbrosus** *Fruhst.* (77 d) every trace of white scaling on the hindwing above has disappeared and the red-brown on the underside of the hindwing is more extended and suppresses the white bands, of which only red-brown-powdered streaks remain. Pulo *eurydice.* Tello, near Nias. — In **eurydice** *Btlr.* even these vestiges of white disappear beneath and the hindwing is unicolorous red-brown with black-brown distal border, which bears the usual double row of white dots. *keteus.* Nias, very rare. — Finally, in **keteus** *Hag.* the white roundish subapical patches of the forewing also begin to disappear, being scarcely half as broad as in *umbrosus*, but the hindwing has beneath a slightly lighter *pietersi.* tinge round the cell. Mentawej Islands. — **pietersi** *Doh.* (77 c) has the forewing elongated instead of rounded, and the weakly developed whitish subapical patches are powdered over with grey-violet, which is unique among the Danaids, but which unfortunately is not sufficiently brought out in the figure. On the hindwing the black suffusion of the upper surface is again reduced in order to make room for a brown cell-centre and interneural stripes of the same colour, which on the under surface moreover are more *melanippus.* copiously shaded with white. Engano, common. Flies principally in April. — **melanippus** *Cr.* is somewhat smaller than *pietersi*. Forewing light yellow-brown as in *indicus* and with narrower white subapical band. Hindwing similar to that of *pietersi*, but lighter brown. The double row of white subterminal dots almost as strongly expressed as in *indicus*. Examples also occur, especially in the ♀♀, with narrow white vein-stripes on the hindwing, which especially beneath are frequently more extended. Java, especially in the *malossona.* west of the island up to about 700 m. — **malossona** *Fruhst.* is the most easterly of the known *melanippus*-races, which are wanting in some parts of the Micromalayan region. Only one ♀ has hitherto been taken, which I brought from Toli-Toli in North Celebes. Forewing with light red-brown tinge in the cell and disc, very distinct white spots at the apex of the cell and even broader white oblique band than *indicus*. Hindwing with pure white cell and very long, broad interneural areas powdered with reddish at their edges. Under surface of the forewing light red-brown with whitish patches, that of the hindwing with reddish costal margin and blue-white areas, which have distally a red-brown border of medium breadth.

haruhasa. **D. haruhasa** *Doh.* (= erebus *Röb.*) is a peculiar species, a sort of intergrade between *melanippus* and *ismare* in its projecting apex and narrow forewing. The forewing is somewhat more pointed than even in the very long and narrow-winged *pietersi Doh.* from Engano, and its ground-colour is a peculiar sepia-brown. The subapical band of the forewing, which is violet instead of white in *pietersi*, is reduced in

haruhasa to 2 white dots. Sumbawa, Flores, Lombok at elevations of 300—800 m.; very rare. — **taimanu** *Doh.* is a smaller, round-winged race with broad white oblique band on the forewing, finely divided by black veins. Ground-colour lighter yellow than in the preceding race. Sumba, at about 300 m. Very rare; DOHERTY only took 2 examples and only one is known to me from Dr. MARTIN'S collection. Both the *haruhasa*-races inhabit the mountains, in contrast to the rest of their allies, in particular *melanippus Cr.*, which frequents the sea-shore. On Lombok they did not fly like ordinary Danaids, but rested on the flowery tops of tall trees, ready to fly away in all haste at the least disturbance to quite inaccessible heights; this may be the reason why they were so seldom caught. DOHERTY believed that he had identified *haruhasa* with „Nasuma" *ismare Cr.* The arrangement of the white dots on both wings and even more the long and narrow interneural streaks of indefinite colour, however, prove that it belongs to *melanippus*: this is also indicated by the red-yellow colour of the abdomen, which is ringed above very broadly with black, beneath scarcely perceptibly with white, whilst *ismare* has the abdomen almost pure white beneath. Valve similar to that of *melanippus*, but without the beak-like curve at the tip. *taimanu.*

D. lotis approaches the forms of *melanippus* so closely that it might be regarded as the representative race from the Philippines, Borneo and Celebes (its area of distribution), were it not that *melanippus* has been recently discovered on Borneo by SHELFORD and is represented on Celebes by *malossona Fruhst.* Hence although *lotis* only differs from *melanippus* in the colouring and in having the strigae before the apex of the cell of the forewing somewhat larger and always distinct, it will most likely prove to be a good species. Probably *lotis* is a phyletically younger branch of the *melanippus*-group, which has undergone a parallel development to *melanippus*, much as *philene* occurs on the Moluccas together with *affinis F.* Valve only differing very slightly from that of *melanippus*, somewhat broader and distally not bent back. The name-type **lotis** *Cr.* was already known to that author from Borneo: it bears narrow white streaks on both wings, which are bounded by broadly black veins. The forewing has beneath a fleshy red tinge along the veins. Habitat South and North Borneo with the exception of the extreme north. — **mezentius** *subsp. nov.*, from Sandakan, which also occurs on a few neighbouring islands, such as Balabac, is distinguished by much broader white transverse and subapical bands on the forewing and more extended interneural streaks on the hindwing. On the under surface of both wings the white spots are more extended, while the black veins of the hindwing only traverse the median area as thin lines. — **edmondi** *Boug.* is a still more pronounced albinotic form from the northern Philippines, where it is very common. The subapical double row of whitish patches on the hindwing are also widened. — **philozigetes** *Fruhst.* is a darker form from the southern Philippines, in which the veins are again somewhat more extended black and the submarginal spots of the hindwing are in size about halfway between those of *mezentius* and *edmonti.* Bazilan, Mindanao, Palawan. — **celebensis** *Stgr.* (= fruhstorferi *Röb.*) is a larger form with very long but narrow subapical streaks on the forewing and especially distinguishable from all the previously mentioned races of *lotis* in having the veins of the forewing both above and beneath broadly striped with red-brown. *celebensis* was described from Minahassa and has not yet been observed further south than Toli-Toli. — **lotina** *Fruhst.*, from the Natuna Islands, forms a connecting link between all the above named geographical races in the broad subapical patches of the forewing, the reddish vein-stripes of the forewing (recalling those of *celebensis*, but weaker) and in having the streaks of the hindwing very narrow, as in *lotis.* — All the non-Philippine subspecies of *lotis* are among those winged evidences which recall to our remembrance the vanished bridges of land from Mindanao to Borneo and from Mindanao to Celebes. *lotis.* *mezentius.* *edmondi.* *philozigetes.* *celebensis.* *lotina.*

D. philene forms the natural continuation of the *plexippus-* and *melanippus*-series and begins to occur at the eastern extremity of their ranges, inhabiting the Moluccas and parts of New Guinea as well as its adjacent islands. Above the *melanippus*-marking is still present, but beneath *philene* differs from its western allies by the broad streaks of modified scales which accompany the veins of the hindwing. Some *philene*-races recall *affinis* by the presence of white cell-dots and whitish circumcellular patches. — **philene** *Cr.* (76 d), the name-type from the southern Moluccas, is very common on Ceram, Amboina and the Uliassers and extends northwards to Buru. Each sex occurs in 2 forms, a dark red-brown and a light red-yellow, the latter usually bearing also more or less distinct small white spots in and around the cell of the hindwing (f. **luxurians** *Fruhst.*) (76 d) and occurring everywhere together with the dark typical form. Valve with distinctly rounded tip, but without the beak-shaped tip of the *melanippus*-type. — **oros** *Fruhst.* (76 d), from Obi, is a melanotic race with the white oblique band of the forewing much reduced, especially in the ♀♀, being almost suppressed by the predominant black ground-colour, so that its separate spots begin to be isolated. Veins of both wings more broadly black, as also the distal border of the hindwing, from which more distinct black teeth run out into the middle of the wing. — **nubila** *Btlr.*, a larger race, inhabits the northern Moluccas and is as a rule darker red-brown than *philene*, with fewer white dots on both wings and more sharply defined distal border to the hindwing. Batjan, Halmaheira, very common. — **subnubila** *Fruhst.* is somewhat smaller. Both sexes are in size intermediate between *rubrica Fruhst.* from Palau and *nubila Btlr.* from Batjan, and in colouring approach *transfuga Fruhst.* White subapical oblique band of the forewing considerably narrower than in *nubila*, but broader than in *luxurians.* *oros.* *nubila.* *subnubila.*

oros Fruhst. from Obi, forewing with only a narrow red-brown stripe, which again is broader than in *transfuga* and narrower than in *nubila* and *oros*. Black distal border of the hindwing very broad, forming
transfuga. a transition from *transfuga* to *nubila*. — **transfuga** *Fruhst.* (= batjana *Fruhst.*), locality unknown (Morotai, Sula Islands?), is the darkest race known, in which the red-brown in the cell of the forewing is suppressed by the black apical and costal colour. Hindwing blackened as far as the cell by the confluent vein-stripes, the white patches of the forewing on account of their small size even more isolated than in *oros*. — At
obscura. the Museum in Brussels examples from Waigeu are labelled **obscura** *Capr.*, but whether the form has really been described I have not been able to ascertain. Cell of the forewing somewhat less blackened than in *transfuga*, the white oblique band of the forewing as a rule strikingly broad, much more extended than in *nubila* and *transfuga*. The form *luxurians* occurs commonly together with the red-brown typical
pseudo- form. Waigeu, not rare. — In **pseudophilene** *Fruhst.* the melanotic colouring proceeds still further. In the
philene. ♂ the upper surface of the forewing is characterized by the more extended black ground-colour, which has completely suppressed the red-brown stripe in the cell of the forewing of *philene* and its allies. The spots between the median veins of the forewing are tawny instead of red-brown. The veins of the hindwing are so broadly edged with black as to reduce the dark brown interneural stripes, on the other hand the black distal bordering of the hindwing is less distinct than in *philene Cr.* and *obscura Capr.* Under surface: apical area brown-black instead of deep black as in *philene*, the basal half of the forewing dull tawny. The veins of the hindwing accompanied by less prominent vein-stripes, which are more grey than black. The submarginal double row of white dots brighter than in *obscura Capr.* Abdomen above black-brown,
molyssa. beneath buff-brown. — **molyssa** *Fruhst.* (77 e) replaces *philene* in British New Guinea, ♂ of black ground-colour with dark chocolate-brown stripes in the cell and between the veins, over which a peculiar reddish violet sheen is diffused. The oblique band of the forewing pure white, very distinct, broader than in *woodlarkiana* and in *ferruginea Btlr.* Hindwing only with a submarginal row of white dots. Under surface: almost uniform dark tawny with only slight traces of an apical tinge. The submarginal oblique band is composed of longer white spots than in *woodlarkiana*. These spots are, however, somewhat narrower and shorter than in *pseudophilene* and *ferruginea Btlr.* The veins scarcely perceptibly accompanied by deep black scent-stripes. The submarginal double row of white spots very distinct. From Collingwood Bay or the islands off it, ♂-type bought in London. *molyssa* forms the darkest extreme of the *philene*-series and at the same time a transition to *ferruginea Btlr.*, from which, however, it may be distinguished by the
woodlar- conspicuously black colouring and the projecting apex of the forewing. — **woodlarkiana** *Fruhst.* very nearly
kiana. approaches *molyssa*. ♂: the white subapical spots of the forewing somewhat larger then in *mytilene Fldr.* from Dorey and *kiriwina Fruhst.*, narrower and more rounded than in *ferruginea Btlr.* and *molyssa Fruhst.* Hindwing: somewhat more copiously striped with dark chocolate-brown than *pseudophilene*. The black, very broad distal border more pronounced than in the Sorrong form. The submarginal white dotting very indistinct. Under surface: basal half of the forewing lighter and more extended brown than in *pseudophilene*. Hindwing: the interneural stripes shorter and lighter; beyond the cell two white spots (much as in *bonguensis Fruhst.*, *kiriwina* and *fergussonia Fruhst.*). Veins bordered by very broad, grey-black scent-
mysolica. scales. Abdomen above black, beneath pale brown. Woodlark Island. — **mysolica** *Moore*, described from Mysol, probably also occurring on Salawatti, is unknown to me in nature, according to the description it
rubrica. approximates to *obscura* from Waigeu. — Finally, **rubrica** *Fruhst.* is a dwarf form from the remote Palau Islands. ♂: smaller, wings more rounded, hindwing more broadly margined with black than in *nubila Btlr.* from Halmaheira and Batjan. The subapical transverse band of the forewing consists of 5 instead of 6—7 white spots. The upper spots are closer together, more uniform, the lowest on the other hand is removed distad further out of the row and is quite isolated. Under surface: the basal red of the forewing distally more sharply defined by the black apical border, the white dotting on the forewing reduced. Scent-stripes of the hindwing along the veins narrower, hence the red-brown spots more extended. — In
bonguensis. German New Guinea *philene* appears to be represented by **bonguensis** *Fruhst.* (77 e), which was formerly regarded by other authors as well as myself as belonging to *mytilene* (77 e), but an examination of the clasping organs has shown that it is not allied to *mytilene*, the valve being almost three times as broad and the uncus essentially more strongly built and at the proximal end of almost quadrate form, not gently rounded like the uncus of *mytilene*. In common with *philene bonguensis* produces specimens resembling the form *luxurians*, as shown in the figure. But the commonest examples are those of unicolorous tawny colour without discal spots, and even without the submarginal spots of the hindwing. According to Hagen *bonguensis* flies from December to April, then again in July and August, and ascends to about 800 m. The true *mytilene* or a sister-race has not yet been met with in German New Guinea, so that Kaiser-Wilhelmsland is poorer in species of this group than the neighbouring British New Guinea and also tho Dutch part of the island.

mytilene. **D. mytilene** *Fldr.* (= pullata *Btlr.*) (77 e) is apparently not very rare in Dutch New Guinea. It is easy to recognize by the small scattered subapical patches of the forewing and the light brown areas breaking up the dark brown ground-colour, which unfortunately do not come out well in the figure. The

under surface is like the upper, except that the basal area of the forewing is somewhat lighter and the veins of the hindwing are accompanied in most specimens by streaks of feebly glossy black-brown, modified scales. Valve strikingly pointed, almost snout-shaped, uncus elongate-cylindrical, covered with scars bearing long bristles. Dorey, probably also other localities of Geelvink Bay. — **decipiens** *Btlr.*, which occurs very commonly on the Solomon Islands, I regard as certainly belonging to *mytilene* on account of the light brown areas on the upperside of both wings; it is smaller and bears in the disc of the hindwing, especially on the under surface, large oblong, mostly rectangular white spots. Moreover, the proximal row of submarginal patches is more sharply marked, whilst the outer row is composed of small white dots. Uncus relatively short, distally sloping, valve with snout-shaped tip. *decipiens.*

D. ferruginea *Btlr.* appears to replace *mytilene* in British New Guinea. Ground-colour uniform dark brown without light patches, the subapical white oblique band similar to that of *molyssa* (77 c), only still more pronounced. Veins of the hindwing beneath nearly always without scent-stripes. Milne Bay. — **kiriwina** *Fruhst.* (77 e) has again very small, isolated white subapical patches. Also the marginal dots of the hindwing are much reduced. Both wings are somewhat lighter in the distal part of the disc, but do not show the glossy areas of *mytilene*. Under surface even lighter than above, the basal half of both wings washed-out, reddish yellow-brown. Cell of the hindwing surrounded by small white patches. Submarginal dotting more delicate than in *ferruginea* and *mytilene*. Kiriwina. Valve shorter without distinct distal beak-shaped prolongation. Uncus more uniform, without dorsal slope. — **fergussonia** *Fruhst.* Both sexes larger than the preceding and *ferruginea Btlr.*, the subapical row of spots consists of rather large, white oblong spots, which reach approximately the size of the corresponding patches in *ferruginea*. The ground-colour is even considerably lighter than in *kiriwina*, moreover the circumcellular spots in the disc of the hindwing, which show through distinctly from beneath, are larger and more numerous. Under surface of the wings paler, which is especially noticeable in the basal area of the forewing. The veins of the hindwing surrounded by more extended and lighter grey scent-rays than in *kiriwina*. Fergusson, D'Entrecasteaux Island. — **pittakus** *Fruhst.* Lighter brown than *mytilene* and *ferruginea*, but without the discal pale tone peculiar to *fergussonia*. The white subapical spots are more isolated. The submarginal white dots more prominent than in the other races of *mytilene* and more elongate. Locality unknown, probably islands in Geelvink Bay. — **jobiensis** *Gr.-Sm.* very nearly approaches *pittakus*, the white subapical band of the forewing is composed of smaller oblong patches and the veins of the hindwing are covered with broad stripes of androconia. Islands of Jobi and Roon, in Geelvink Bay. — **adustus** *Godm. & Salv.*, described from New Mecklenburg, I think should also be included here. Like *decipiens* of small size, with strongly rounded forewing, the pale brown ground-colour approximates closely to *kiriwina*. The subapical patches of the forewing are reduced to dots and the hindwing bears only beneath small white circumcellular patches. Common everywhere in the Bismarck Archipelago. — **biseriata** *Btlr.*, from New Lauenburg, is scarcely distinguishable from *adustus*, which was described four years earlier. According to the ♀ before me it appears to be a dark brown dwarf form. — **insolata** *Btlr.* is a race from the Solomons, described without more exact locality in a book of travels, and bears somewhat more distinct white spots than *adustus*. *ferruginea.* *kiriwina.* *fergussonia.* *pittakus.* *jobiensis.* *adustus.* *biseriata.* *insolata.*

D. affinis and its allies form a group in which the streaks of androconia or otherwise modified scales do not directly accompany the veins, but are partially separated from them by white streaks. Valve in the Australian races with somewhat more obtuse tip than in the superficially much modified west Malayan subspecies. Uncus extremely delicate, palpi-like, ornamented with fine cilia. The name-type comes from Australia. Altough *affinis* occurs from the Solomons to Java and the Malay Peninsula, from the Philippines to Bonerate, thus covering a wider range than *plexippus L.* and with the exception of the Moluccas, where it is wanting, flies everywhere together with *plexippus*, some authors cling to the idea that *affinis* is only a „variety" of *plexippus*. *affinis* is doubtless one of the few species which have migrated westwards from Australia and spread as far as the Malay Peninsula. — **cometto** *Godm. & Salv.* is a form from the Solomons; I found the name in the British Museum, but have not hitherto been able to trace its source. — **affinis** *F.*, the name-typical subspecies, inhabits tropical Australia, the Aru, Key and neighbouring islands and is also in my collection from Banda and Goram. ♂♂ distinguished from the figured *affinoides*-♂ (77 d) by the absence of the white cell-streak in the forewing and the paler white submarginal dots on the upperside of the hindwing. In the ♀♀ the white area of the hindwing is somewhat broader. On the Aru Islands and also in the *affinis*-race from West Dutch New Guinea melanotic examples also occur, though very rarely. f. **vorkeinus** *Röb.* (named from Vorkein, a place on Aru), in which the white areas of both wings are densely dusted with black and the one placed between the medians of the forewing below the cell almost entirely suppressed. — **galacterion** *Fruhst.* On the Fergusson Islands *affinis* is modified by having the white subapical macular band of the forewing and the circumcellular patches of the hindwing more extended. Under surface: the white in the middle of the forewing begins to be covered with reddish scales and the submarginal wedge-spots of the hindwing are red-brown instead of yellowish as in *affinis*. Hence we find in *galaeterion* lighter and more extended white markings on the upperside to- *cometto.* *affinis.* *vorkeinus.* *galacterion.*

gether with a darkening of the underside. Fergusson, D'Entrecasteaux Islands. — **strephon** *Fruhst.* are examples from New Guinea, which are intermediate between *affinis F.* from Australia and *galacterion* in the shape of the white oblique band of the forewing and in the red-brown of the wedge-spots on the hindwing beneath, which is somewhat lighter than in *galacterion*, but yet always darker than in *affinis*. Localities: Etna Bay and Kapaur, South-West Dutch New Guinea, discovered by H. Kühn and W. Doherty. In *strephon* also the form *vorkeinus* appears as an aberration. — **affinoides** *Fruhst.* (77 d) most nearly approaches *affinis F.* from Australia and Key, but differs from it in the ♂♂ by having both wings more copiously sprinkled with white, and in the broader oblique band and the broad white cell-streak on the forewing above. Under surface: the apex of the forewing is brown and not black and the hindwing shot with dark coffee-brown, not light reddish brown. Locality: Talaut Islands to the north of Celebes. Whilst *affinoides* very closely approximates to the Australian type, a race from the island of Taruna, likewise belonging to the Talaut Islands, differs so strikingly from *affinis* that we might almost think we had a separate species before us, if transitions like *decentralis* (77 d) did not prove that in *affinis* the black ground-colour very easily changes into dark red or even into light yellow-brown. At any rate **taruna** *Fruhst.*, from the harbour of that name in the island of Sangir, closely resembles *decentralis* (77 d), is much larger and bears only an indistinct white spot before the inner margin of the forewing and a shorter white spot in the cell of the hindwing. The under surface of the forewing is light red-brown without a trace of discal spots. — **sangira** *Fruhst.* is only a form of the preceding, nearly approaches *taruna* in size and has also about the same pattern, except that it bears a very long white spot between the lower median and the submedian of the forewing, larger white cell-spot and elongated white circumcellular patches on the hindwing. Sangir. — **decentralis** *Fruhst.* (77 d) inhabits all the islands of the Peling and Sula Groups to the east of Celebes, where it is very common everywhere. Smaller than *sangira*, it bears a much narrower white subapical band on the forewing, also in many examples there are white cell-streaks on the forewing, but even the specimens with the upper surface most darkened bear nevertheless a very long and broad white spot above the submedian of the forewing beneath, in which *decentralis* differs constantly from **fulgurata** *Btlr.* from southern and eastern Celebes. Many *fulgurata* have no white at all on the forewing and even the small cell-spot of the hindwing is sometimes dusted over with black. — An interesting form is **leucippus** *Röb.*, from Kisser and Wetter, whose ground-colour is predominantly white with the usual black margins to the wings and some light yellow-brown stripes on the upperside. The hindwing bears beneath large tan-coloured roundish submarginal patches, which sometimes extend in arrow-shape nearly to the cell. — **chionippe** *Hbn.* is a very nearly allied race from Timor, in which the white subapical band of the forewing and the disc of the hindwing are even more broadly white. — **coriacea** *Fruhst.*, from Alor, on the contrary is a form in which the white of both wings is changed into light tan-colour, on the forewing sometimes even completely gives place to it. The underside of the forewing shows no trace of a white patch. — Thus the race from Alor forms a transition to **tambora** *Fruhst.* (77 d), in which the forewing always remains uniformly yellow-brown. The white area of the hindwing is likewise less extended than in *coriacea* and *chionippe*. Sumbawa, Lombok. On the latter I observed *tambora* in May exclusively at the edges of the open woods at the sea-coast and indeed quite near to the sea. A few kilometers inland it seems to disappear. — **hegesippus** *Röb.*, judging by the single ♂ before me, is larger than *tambora* and the white on the hindwing confined to the cell and small patches beyond it. Island of Bonerate, between Flores and Celebes. — **litoralis** *Doh.* is a small race with more rounded wings than *tambora* and the disc of the hindwing more extended and purer white. Sumba. Apparently very common. — **fuliginosa** *Hag.* is a very variable form from Bawean with very broad white oblique band on the forewing and with the hindwing predominantly yellow-brown instead of black. The disc of the hindwing is sometimes only marked with indistinct white patches, so that the wing may be described as red-yellow with small white spots, in many ♂♀ on the contrary the white area suppresses the ground-colour except for a few streaks. An aberration apparently allied to *vorkeinus* has been described as f. **astakos** *Fruhst.* The white subapical oblique band of the forewing, as in *melanippus pietersi Doh.* from Engano, is powdered over with violet, the discal white spots of the hindwing are wanting above and beneath also are only slightly indicated. The wings are elongated and the colouring of the upper surface so much recalls *melanippus Cr.* from Java that one might think it to be a cross between this species and *affinis fuliginosa*, which is, however, naturally precluded by the fact that *melanippus* apparently does nor occur on Bawean. — **kawiensis** *Fruhst.* is a small aberration of *fuliginosa*, it is said to come from the volcano Kawie in eastern Java, but I doubt its locality, as all the allies of *affinis* frequent the coast. The type is smaller than *fuliginosa*, the cell of the forewing somewhat darker than in the race from Bawean, the hindwing bears only a row of white dots and in the disc beneath the white is reduced to a few stripes round the cell. I once saw a similar example in the collection of an amateur in Batavia. — Finally, a further geographical form certainly comes from Java, which indeed gives quite the impression of a distinct species and has been known since 1782, namely **artenice** *Cr.*, described from the neighbourhood of Batavia and Samarang. It is very local and apparently rare, for I have only seen a few examples. *artenice* is a small butterfly of only 50 mm. expanse and with entirely yellow-brown ground-colour. The discal white on the hindwing

strephon. *affinoides.* *taruna.* *sangira.* *decentralis.* *fulgurata.* *leucippus.* *chionippe.* *coriacea.* *tambora.* *hegesippus.* *litoralis.* *fuliginosa.* *astakos.* *kawiensis.* *artenice.*

above which is common to all the other races has entirely disappeared and is scarcely indicated beneath. Hence *artenice* forms the greatest contrast imaginable to **malayana** *Fruhst.* (77 d), a highly specialized form almost worthy of specific rank, of which for a decade only one ♂ was known, whose locality, the Malay Peninsula, was moreover still doubtful. But I found the species fairly numerous in Bangkok, where this beautiful form was not rarely to be met with on the right bank of the Menam on flowers and grasses in the extensive temple gardens near the canals. Thus *affinis*, the most variable of all the Asiatic *Danaida*, has also reached the continent and will certainly extend still further along the sea-coast of Siam. *malayana* bears, as may be seen from the figure, the most white on the hindwing and the median area is sharply defined posteriorly with only a slight yellowish distal tinge. Although the valve is somewhat more pointed than in *affinis*, I have not considered that *malayana* should be separated specifically from *affinis*, even in spite of the considerably different markings, which are connected by transitional forms with the Micromalayan races. — **abigar** *Eschsch.* is the only representative of *affinis* recorded from the Philippines, apparently very local and rare, as it is still unknown to me in nature. According to the figure the hindwing recalls *affinoides* and like the latter is broadly margined with black-brown and without a trace of yellowish markings. The white median area of the hindwing is almost as extended as in *affinoides*, especially on the under surface, which bears red-yellow sagittate spots. The cell itself is entirely white, whilst that of the forewing is margined with reddish and below it two almost obsolete discal spots are placed at the submedian. Only Manila is yet known as locality. A race allied to *abigar* inhabits Mindoro, but only one ♀ is recorded, of which according to Semper „the white parts of the hindwing are more broadly suffused with brown than usual."

malayana.

abigar.

Group Nasuma *Moore* (1883).

Of all the Danaid subgenera *Nasuma* possesses the most claim to be raised to generic rank. The second subcostal vein arising far beyond the apex of the cell; middle discocellular of the hindwing inappreciably concave; androconia-pouch as in *Anosia* approximated to the lower median; uncus short, relatively broad; valve of extremely bizarre form, dorsally with slightly projecting angle, ventrally with a deep sinus, recalling that of *Tirumala*, but still more incised, and sending out a thumb-shaped point ventrally.

D. ismare with its branch-races inhabits exclusively the region of the Moluccas, with a highly specialized offshoot in Celebes. Singularly no *ismare* is yet known from the Sula Islands, between Celebes and the Moluccas, and new subspecies may still be looked for from there. *ismare* has of all the Danaids the most elongated apex to the forewing and as a consequence of this peculiarity the second subcostal also arises the furthest distally to the end of the cell. The name-type **ismare** *Cr.*, originally described from Amboina, also inhabits Ceram and the Uliasser Group, from which it has been brought to Europe in large numbers by Captain Holz, especially from Saparoea. Forewing longer and ornamented with much smaller patches, which are grey-white, than the figured *fulvus*. Forewing of the ♀ somewhat rounded, all the patches and streaks more extended and lighter grey-white. Both sexes bear a very large whitish spot before the apex of the cell of the forewing, by which it can easily be distinguished from all the other known *Danaida*. *ismare* is not very common and is inclined to produce gynandromorphs, two of which have already been made known and figured by Butler and Dr. Haase. — **ismareola** *Btlr.* Both sexes smaller than *ismare*; ground-colour brown with broader white markings. Ternate, Halmaheira. — **felicia** *Fruhst.* (76 e). Both sexes are intermediate between *ismareola* and *ismare*, of smaller size. All the white markings are more extended, in the hindwing above there is not a trace of a brown-black double line, the circumcellular and submarginal spots strongly pronounced. Obi, Buru. — **goramica** *Fruhst.* differs from *ismare*, apart from its smaller size, in the presence of a white streak in the cell of the forewing and the larger transcellular spots of both wings. In the cell of the hindwing there are still the remains of a thin forked marking. *goramica* forms a transition between *felicia* and *ismare*, is lighter than *ismare*, but has much less white marking than *felicia*. Goram. — **fulvus** *Ribbe* (= celebensis *Rothsch.*) (76 c) inhabits Celebes and its satellite-islands and in my experience never extends beyond the woods on the coast. In North Celebes I observed the butterflies as they flew from Toli-Toli to the islet of Lutungan, about 2—3 km. off, sailing rapidly high over the sea, sometimes accompanied by white *Delias* and the swift-winged *Acraea dohertyi*. On Lutungan itself they led a leisurely life, visiting the flowers of low shrubs in the shade of high trees and being so little shy that they could then almost be taken with the hand. *fulvus* occurs in two seasonal forms, of which we figure that of the dry season (76 c). The rainy-season form differs in the yellowish instead of blue-white apical spots of the forewing and submarginal dots on the hindwing, also the whitish circumcellular stripes on the hindwing sometimes become yellowish. In a ♂ from Sangir in my collection the underside of the hindwing is also differently coloured, the whole surface being slightly tinged with yellowish.

ismare.

ismareola.

felicia.

goramica.

fulvus.

Group Tirumala *Moore*.

Larva with 2 pairs of tentacles (as in *Anosia*), but with lateral ventral stripe; androconia-pouch of the hindwing removed further from the lower median, much larger and produced into a long, dome-shaped appendage. Valve without horizontal prolongation, but with a spine-shaped, ventral vertical point. Lower discocellular of

the hindwing longer than the middle one. The group is bicontinental and in the tropical zone extends from West Africa to Australia and far into the South Sea and presents considerable difficulties to the systematist on account of the great similarity of the few species with their many forms. Although the species are mostly among the commonest butterflies, the complete life-history of only one is known.

D. melissa is one of the most widely distributed species of the eastern Rhopalocera, being found in an uninterrupted chain of local forms in the whole of South and East Asia, as well as the islands of Ceylon and Macromalayana to the most remote South Sea Islands. The differentiation of the forms of the species has occasioned great difficulties, as the island of Java produces two forms, of which one had been already described by CRAMER (*melissa*), and is continued in the whole eastern (Micromalayan) district, whilst a second is closely allied to the continental type (*septentrionis*). But examinations of the genitalia have shown the specific identity of these very diverse forms. Only the uncus shows a slight difference, being in *septentrionis* sharply truncate distally, in *melissa* slightly convex. The valve is likewise distally sharply truncate vertically and bears a finger-shaped spine with obtuse point, which varies somewhat in length according to the locality. — The continental **septentrionis** *Btlr.* has already been described, vol. I, p. 77 and figured pl. 28 d. It is characterized by long subapical blue-green streaks on the forewing, a thick black cell-streak, which is coincident with the cell-wall and only very rarely incurved distally, and narrow greenish interneural areas on the hindwing. The eggs are laid singly, each on a separate leaf; egg white, globular, much flattened at the point of attachment to the leaf. The larva hatches after 4 days, white with black head. After another two days the first moult takes place, after which the white larva shows black transverse lines and fleshy spines. A week later it ceases to feed, pupating shortly afterwards. Pupa green, with shiny gloss, golden dots and a golden band at the base of the abdomen; scarcely distinguishable from the green of the food-plant. Pupal stage 8 days. A rapid development for so large a butterfly (MARTIN). The butterflies common everywhere, from Kashmir to Formosa, from Tenasserim to Cochin China. Examples from the Malay Peninsula and Sumatra are smaller than North Indian ones. — In South India *septentrionis* is replaced by **dravidarum** *Fruhst.*, a somewhat smaller form, with much lighter general tone of colouring and much broadened interneural areas, which especially on the forewing begin to merge together, so as to form tobacco-pipe-shaped markings. The black streak of the hindwing scarcely half as broad as in *septentrionis*, hence the patches beyond the cell more extended. Common, especially at the Malabar Coast. — In **musikanos** *Fruhst.* (78 a) the insular melanism is revealed in a partial restriction of the white stripes, which, however, are still always considerably broader and essentially lighter than in North Indian examples, as is especially noticeable when series from the different localities are placed side by side. Ceylon. — **rufiventris** *Fruhst.* approaches *musikanos* in size, but in the markings approximates most nearly to *mierostieta* from Borneo, and like this has the dark green vitreous patches more reduced. But the principal characteristic is furnished by the entirely red-brown abdomen, which shows only a restricted black dorsal scaling. Under surface of both wings as dark as the Borneo form (almost black-green). Nias, apparently very rare. — **microsticta** *Btlr.*, from North and South Borneo, constitutes the finest Macromalayan *melissa*-race, in which, especially on the hindwing, the green stripes are reduced to fine vitreous lines. Abdomen above broadly black, beneath red-brown, ringed with white. — **palawana** *Fruhst.* is intermediate between the dark Borneo race and the very small and light one from the Philippines, but unaccountably approximates most nearly to the continental *septentrionis*, though somewhat smaller. The greenish white vitreous spots — although broader than in *mierosticta* — are narrower than in *septentrionis*, and nearly approach those of *rufiventris*. Palawan, apparently rare. — **orientalis** *Semp.* may best be described as a smaller version of *dravidarum*. The patches beyond the cell, however, are smaller, the under surface of the forewing lighter red-brown and the hindwing light yellow-green. The tobacco-pipe is very distinct in the ♂♂, but in the ♀♀ the median-stripes are as a rule isolated. According to SEMPER *orientalis* is very variable, the forms from the South Philippines essentially darker than the lighter specimens from Luzon, but this cannot be definitely settled. — But it is on Java that *melissa* shows the most interesting development. From this island comes the name-type, **melissa** *Cr.*, a smaller form than *septentrionis*, characterized by the broad white stripes on the hindwing, which recall *limniace*. The uncus is distally somewhat sinuate, shorter than in North Indian *septentrionis*, and the point of the valve is similarly modified, i. e. becomes shorter and apparently somewhat ventricose. But together with *melissa* we meet with another form, equal in size to *septentrionis*, which somewhat recalls *microsticta* from Borneo, and on that account has been hitherto confused with it. It may probably be a product of the wet season, and is here called **myrsilos** *form. nov.* The hyaline patches and streaks recall *musikanos* from Ceylon, the cell-streak of the forewing is even somewhat stronger, but the other streaks are somewhat less prominent than those of *musikanos*, being, however, still always about twice as broad as in *microstieta* from Borneo. The colouring of the underside is darker than in the Ceylon form, without, however, attaining the deep brown-green of *rufiventris* or *microsticta*. With *myrsilos* the last reminder of the continental *septentrionis* disappears, and in Micromalayana *melissa* exclusively holds the field, inhabiting all the small Sunda Islands from Bawean and Bali eastwards and occurring wherever a long-continued dry season prevails. The smallest examples are found, as always, on Sumba and Wetter. *melissa* is to

septentrionis. *dravidarum.* *musikanos.* *rufiventris.* *microsticta.* *palawana.* *orientalis.* *melissa.* *myrsilos.*

be met with in immense numbers on Lombok, especially after the rainy season (April—May) in village gardens at about 600—700 m. above the sea, sometimes 5 or 6 specimens rest on a single flower and can be taken with the fingers. — **paryadres** *subsp. nov.* is the race from the Key and Timor-Laut Islands, *paryadres.* which agrees with *ishmoides Moore* from Celebes in the narrow, unusually long subapical streaks and pointed oblong patches in the disc of the forewing. — As **singaria** *subsp. nov.* we introduce the large race *singaria.* from Dammer, recalling *hamata*, which with its large light green patches has much in common with *limniace* and differs from *hamata* in the somewhat narrower subapical streaks and the smaller median spots. — **nigra** *Mart.* was rightly separated on account of its short, thickset, rounded wings and the almost *nigra.* entirely black under surface; it comes nearest to *paryadres*, but has the hyaline patches even less developed. Ceram. — **goana** *Mart.* is a further noteworthy race, which far surpasses its allies from Java and the small *goana.* Sunda Islands in size and is distinguished by peculiar wing-contour, the typical Celebes curve of the costa, very dark ground-colour and large submarginal and marginal spots on the hindwing. Under surface of the forewing as in all the *melissa*-races a beautiful red-brown. *goana* is very rare, only 2 ♀♀ having been discovered in South Celebes, and is either dying out or is an immigrant from the south across the sea of Flores (MARTIN). — **arikata** *subsp. nov.* closely approximates to *nigra*, with which it has the rounded *arikata.* wings in common, but differs from it in the shorter, broader vitreous spots, and particularly in the ♀ in the lighter brown ground-colour. Sula Mangoli and Sula Besi. — **hamata** *Me Leay*, distributed in *hamata.* Australia from Sydney to Cape York and very common in Queensland, almost equals *septentrionis* in expanse, but approaches the races of Micromalayana in the rounded wings and large light bottle-green patches. The submarginal dots of the hindwing are smaller than in *singaria* from Dammer. In coll. FRUHSTORFER *hamata* is also represented from Milne Bay and some of the islands off British New Guinea. From several preparations it appears that *hamata* has the shortest and at the same time the most sharply pointed process of the valve, which is scarcely half as long as in *septentrionis* and *dravidarum*, being also shorter than that of *melissa* from Java. — **phrynichus** *subsp. nov.* is a form from Collingwood *phrynichus.* Bay, in the northern part of British New Guinea, with *limniace*-pattern, probably belonging to the dry season, with the light greenish patches more than twice as broad as even *singaria*. The cell-streak of the forewing in particular is widened and the light markings are reproduced on the underside even more distinctly than above. The tip of the valve shows a retrogression to *septentrionis* and is exactly as long as in this, but somewhat thicker. — **leucoptera** *Btlr.*, described from Dorey, but distributed over the whole *leucoptera.* northern area of Dutch and German New Guinea, differs from *hamata* in the darker green vitreous patches and in having the underside of the hindwing not yellowish or green-grey, but uniformly red-brown. The distal border of the hindwing above, particularly that of the ♀♀, begins to assume a pale blue colour, which sometimes even becomes grey-white. — **gariata** *subsp. nov.* is a darkened form, with the wings in *gariata.* the ♀♀ entirely brown, showing very narrow grey-green vitreous patches. The under surface of both wings is darker throughout, uniformly black-brown, with rows of much reduced submarginal dots. New Mecklenburg, but probably also on other islands of the Bismarck Archipelago and the Solomons. Examples from New Pomerania are smaller than ♂♀ of *gariata* from New Mecklenburg. — **obscurata** *Btlr.*, described *obscurata.* from the Samoan Islands without more exact locality, is unknown to me in nature, perhaps it is a synonym of *melittula H.-Schäff.*, as according to MOORE both occur on Upolu (Samoan Islands). — **melittula** *melittula.* *H.-Schäff.*, judging from a figure of SEMPER, shows some affinity to the Philippine *orientalis* and bears like the latter narrow, but apparently yellowish white stripes on both wings and is of small size, as the name already correctly indicates. Samoan Islands. — **neptunia** *Fldr.*, from the Fiji Islands, has a very *neptunia.* broad brown area in the disc of the forewing. The roundish patch before the apex of the cell and the subbasal whitish cell-streak are absent, and the cell of the hindwing is entirely blackened or dark brown except for the white apex. — **angustata** *Moore* is the race from the Tongatabu Islands and has even *angustata.* narrower white bands and more extended brown areas than *neptunia*. — **claribella** *Btlr.*, described from a ♀ *claribella.* which is said to come from the Fiji Islands, is a form allied to *neptunia* — and **moderata** *Btlr.*, from Vaté, *moderata.* in the New Hebrides, which is intermediate between *melittula* and *neptunia*, completes the series of the Oceanian island races.

D. gautama, an isolated species with *Radena*-like wing-pattern, differs both from *melissa* and from *limniace* in the two white cell-streaks of the forewing and in the black fork of the hindwing being so divided that there are 3 white longitudinal stripes in the cell. The ultracellular streaks of the hindwing are so long as to be confluent with the submarginal patches. By the red-brown tinge of the forewing beneath *gautama* recalls *septentrionis* and by the stripes of the hindwing *limniceae*, with which it has also in common the light yellow-green instead of brown flaps to the androconial pouch. **gautama** *Moore* is appa- *gautama.* rently common in the Mergui Archipelago, rare in the woods at the coast of Tenasserim and Burma. — **gautamoides** *Doh.* inhabits the Nicobars, where it is not rare and flies in company with *Radena nicobarica*, *gauta-* *moides.* presenting a miniature edition of *gautama Moore*.

D. ishmoides *Moore* (= australis *Blaueh.*?) is another island species, likewise allied to *melissa*, but *ishmoides.* distinct, which owes its name to its resemblance to *Radena ishma Btlr.* The whitish transverse streaks of

both wings very distinct, long, the median ones very broad but without being confluent. Margining of the wings dark brown, ornamented with smaller whitish submarginal spots than *melissa*, the marginal dots almost obsolete, in a ♀ from Tondano completely absent on the forewing. Scent-pouch of the ♂♂ beneath black-brown, abdomen above black, beneath predominantly white. Very rare, but occurring both in the north and south of Celebes.

D. limniace, already described vol. I, p. 77 and figured pl. 28 e, inhabits, compared with *melissa*, only a small area, and in consequence is only broken up into a few local forms, which do not extend to the east beyond Celebes, not even reaching the Moluccas. On the continent and in East Asia the range of distribution exactly coincides with that of *septentrionis*, i. e. both occur on Formosa and on the Philippines. It is, however, worthy of note that *limniace* has not hitherto been observed either in Sumatra or on the Malay Peninsula and Borneo, so that there is a gap in its distribution between the Nicobars, where it is found according to De Nicéville, and Java. Also from Nias and Engano *limniace* is not yet recorded, and that it should not have reached Palawan either is only natural, as it is wanting on Borneo, whence it might have crossed over to Palawan. *limniace* is easy to distinguish from *septentrionis* and *melissa* by the much larger, almost pure white spots and stripes on both wings, the median spots of the forewing are confluent and almost always form the tobacco-pipe figure, especially in the island races. Abdomen above lighter than in *melissa*, beneath predominantly grey. Scent-flaps of the ♂♂ beneath light yellow-brown with dark brown border. The cell of the hindwing bears only a thin fork, which may also be entirely wanting. The valve is very different from that of the *melissa*-series of forms, yoke- or side-saddle-shaped, distally not with a sharp spine, but armed with strong angular teeth. Uncus more robust, sometimes smoothly truncate distally. — The larva has been described in vol. I: it lives on Asclepias, Calotropis, Hoya; when touched it rolls itself up and feigns death. Whilst feeding it holds on by means of a fine web extending from the forelegs. — Pupa at first green, but after a day or two numerous shiny gold dots
limniace. and a raised belt of the same colour appear. — **limniace** *Cr.* occurs chiefly in the plains, but ascends in India at some places in the Himalayas to 6000 ft., is fond of resting in crowds on low bushes and often drinks at wet places on the road. Examples from China, Hong-Kong and Formosa are somewhat larger and darker, those from South India and Ceylon are appreciably lighter, so that Ceylon examples may be
mutina. introduced as **mutina** *subsp. nov.* (78 a). The black cell-streak of the hindwing is nearly always absent, the vitreous patches of the forewing are shorter but broader, likewise the submarginal dots of the hind-
leopardus. wing are enlarged. As **leopardus** *Btlr.* a colour-aberration has been described which has golden brown
conjuncta. hindwing: probably based on a specimen altered by external influences. — **conjuncta** *Moore* is a yet smaller race than *mutina*, distributed from Java to Celebes in the Micromalayan region, and as a rule shows a light red-brown tinge on the forewing beneath, recalling *melissa*. Cell of the hindwing with distinct bipartite cell-streak. There occur quite small, dwarfed examples and also forms with the cell of the forewing entirely white and supplementary transcellular spots on the hindwing almost 1 cm. in breadth
donia. (f. **donia** *Fruhst.*). On Lombok *conjuncta* is very common at altitudes of 500—700 m., always in company with *melissa*, and sometimes 3 or 4 on one flower on weeds in the village gardens, both sexes so sluggish that they can be taken with the fingers. The natives often brought me 2—300 specimens in a single morning: defective examples which one throws away are not eaten by fowls any more than *Pap. sarpedon*,
makassara. *aristolochiae*, *Delias oraia* and Euploeas. — **makassara** *Mart.* most nearly approaches *conjuncta Moore* from Java, with which it also agrees in size: but has the marginal area of both wings more copiously spotted than *conjuncta*, in which latter the black marginal bands are larger and more uniform. On the under surface of both wings *makassara* is pretty uniform blackish, whilst in most of the other *linmiace*-forms a golden brown tinge is spread over the hindwing and the apex of the forewing. Single specimens of *makassara* indeed show a slight trace of the golden brown tone, but always much less than in *conjuncta*. The hyaline spots of the under surface, which in *conjuncta* are bluish on the forewing, but on the hindwing white, especially towards base and anal margin, show in *makassara* no difference in colour, but are slightly greenish white on both wings. The scent-pouch of the ♂ is whitish grey with a dark apical border. Abdomen above grey-brown, beneath red-yellow with whitish rings and lateral small white dots and the rudi-
bentenga. ments of a white ventral line. South Celebes, neighbourhood of Macassar. — **bentenga** *Mart.* (78 a erroneously printed *bengena*), the darkest form of *limniace* known, with deep black ground-colour, in size approaching the continental forms, but with broader, shorter wings. The black marginal area of both wings very broad, with the marginal and submarginal spots much reduced, even surpassing *conjuncta* in this respect; on the upper surface of the hindwing the spot placed in the fork between the upper and middle median veins, in other forms shaped like a V opening posteriorly and distally, is so much reduced that it only appears as a small cap. In no other form of *limniace* do we observe a like reduction of this mark. As regards the hyaline spots the under surface has the uniform colouring of *makassara*; distal area of the hindwing and apex of the forewing possess the golden sheen of the other *limniace*-forms, only it is not golden brown, but of a darker gold-olive shade. The basal part of the forewing beneath is very black, more so than in any other form of the species. Scent-pouch of the ♂ light grey with broad black border;

abdomen above black, beneath brown with faint white rings and an interrupted whitish ventral stripe. Moreover, the valve of this distinct island race, which so unexceptedly intervenes between the light *conjuncta* of Kalao and South Celebes, shows differences from *limniace*. It is flatter in shape, without widely projecting ventral teeth, but more trough-shaped, with long bristles. Uncus very large, warty. — **orestilla** *subsp. nov.* is hitherto only known from Luzon and next to *donia* is the lightest extreme yet observed, the black margin of the hindwing is much reduced, the circumcellular spots are widened also between the median veins, and the discal spots of the forewing are so much enlarged as to be almost united with the submedian tobacco-pipe figure, — **ino** *Btlr.*, a pygmy form with the distal border almost entirely blue-black, especially on the hindwing beneath, the white spots before the apex of the cell of the forewing much reduced and roundish submarginal dots on both wings, so much resembles *choaspes* that 10 years ago I took it for a *choaspes*-race. But the red-brown abdomen only lightly ringed with white in conjunction with the roundish instead of elongate, pointed, subapical patches shows distinctly that it belongs to *limniace*. Very rare. Sula Mangoli. *orestilla.* *ino.*

D. choaspes (78 b) is a highly specialized species which exclusively inhabits the Celebes-Philippine region; three branch races are known to me and we may still expect new additions from the satellite islands. The species is distinguished from *limniace*, with which it has otherwise much in common, by the pure white abdomen, which bears only a narrow black dorsal line. The subapical streaks at the end of the cell of the forewing are elongate, but are mostly wanting in the ♂♂, and also in both sexes of the Philippine race. The bottom of the tobacco-pipe is also absent owing to the suppression of the 3rd proximal submarginal spot of the forewing. — **choaspes** *Btlr.* is very constant, apparently not occurring in the north of Celebes, and with no tendency to develop seasonal forms. Scent-pouch of the ♂♂ black. Flies all the year round, occurs more freely in the rainy season from October to February, but is never common. — **kroeseni** *Mart.* is smaller than the Celebes form, from which it is distinguished by the violet-black ground-colour (green-black in true *choaspes*) and by the complete absence of the brownish green tinge on the apex of the forewing and the distal border of the hindwing beneath. Only 1 ♂ from the island of Buton, discovered by Dr. Martin. — **tumanana** *Semp.* is a characteristic local form almost worthy of specific rank. The distal subapical patches of the forewing very broad and also the spot below the apex of the cell, the stripe at the submedian of the forewing removed quite near to the base of the wing. Hindwing, however, as in *choaspes*. Likewise very rare, only 2 ♂♂ known from Tumanao, an island off South-East Mindanao. *choaspes.* *kroeseni.* *tumanana.*

Group Ravadeba *Moore* (1883).

(*Ashtipa, Bahora, Phirdana Moore*). The second subcostal vein of the forewing arises before the apex of the cell. The lower discocellular of the hindwing very short, vertical, not oblique as in the preceding groups. At the lower median vein a large patch of androconia, which is not affected by chlorated water. Uncus palpi-shaped, small, narrow, in one species (*cleona*) recalling willow-catkins. Valve varying from one species to another, distally with a prolongation resembling a fox's head. Larva with 2 pairs of tentacles.

D. aspasia, a typical Macromalayan species with only one offshoot to Palawan, which in other respects is also mainly Malayan. Nowhere rare, this flower-loving species on the other hand never occurs commonly or in large companies; it scarcely ascends above 700—800 m. and favours the edges of the woods, the ♀♀ even fonder of the shade than the ♂♂. **aspasia** *F.* (= crocea *Btlr.*) (76 d), of which the type (preserved at the British Museum since 1787) probably came from Siam, where I rediscovered the species. Also inhabits Palawan and the Malay Peninsula, and extends northwards to southern Tenasserim. All the localities formerly given, such as Assam or even Nepal, are altogether incorrect. But probably *aspasia* also inhabits the extreme north-east of Sumatra. ♀ with more rounded forewing, almost entirely transparent cell and larger hyaline and yellowish patches on the forewing than the ♂. — **thargalia** *subsp. nov.* is a hitherto unnoticed form of western Sumatra, which very singularly shows much lighter, i. e. less blackened, cell on the forewing than *aspasia*. Both sexes bear moreover broadened vitreous streaks on the forewing. The elongate interneural area above the submedian of the forewing is only very slightly tinged with yellowish, its upper and distal part entirely vitreous in both ♂ and ♀. — **philomela** *Zink.-Somm.* (76 e) has the cell of the forewing completely filled up with yellow and predominantly yellowish subapical stripes, which in both sexes are much shorter and broader than in *aspasia* and *thargalia*. Also the intramedian ultracellular patches of the ♂ are yellow, in contrast to *aspasia*, where they remain white. Valve with thick snout-shaped process, armed with scattered bristles, ventrally as in *limniace* with a trough-shaped incision. *philomela* is not rare in eastern Java, where it enlivens especially the edges of the coffee-plantations and open woods at elevations of about 500—800 m. — **rita** *Fruhst.* bears again somewhat lighter and broader subapical transverse stripes and larger subapical patches, particularly on the hindwing. Island of Bawean, to the north of Java. — In **chrysea** *Doh.* there is an increase in the yellow areas, the forewing of the ♂♂ showing only yellow patches, that of the ♀♀ already yellow intramedian areas. Engano, common in April. — In **kheili** *Stgr.* the yellow colouring reaches its maximum, all the *aspasia.* *thargalia.* *philomela.* *rita.* *chrysea.* *kheili.*

vitreous patches in both sexes being a beautiful dark yellow, only the distal row of the submarginal patches and a part of the proximal row remain white, which is still more noticeable beneath than above.

shelfordi. Nias, apparently rare. — Finally, **shelfordi** *Fruhst.* presents a reversion towards *aspasia*, having the cell of the forewing in the ♂ almost completely blackened, in the ♀ vitreous, and differing from all the *aspasia*-forms in the very small amount of yellow on the forewing, which is only present below the submedian. North and South Borneo.

In the Moluccan subrégion *aspasia* is replaced by **D. cleona,** which forms a similar series of insular forms as its Malayan relative. Wings somewhat more rounded, habitus in general larger, valve with thicker tip, more densely covered with bristles. Uncus shorter, consisting of 2 rounder and more cylindri-

luciplena. cal parts, which likewise bear fine bristles. — **luciplena** *subsp. nov.*, from Celebes, nowhere rare either in the north or the south of the island, is the darkest and most uniform yellow in colour and in it the ♀

eucleona. does not differ from the ♂ except for the more rounded wings. — **eucleona** *Fruhst.* (76 a) has somewhat more extended subapical streaks on the forewing and rather more pointed circumcellular areas on the hindwing. ♀ likewise similarly coloured to the ♂, but lighter yellow (76 a ♀). The intraneural areas of the ♀

cleona. are almost confluent and on the hindwing are not pointed distally but broadly lobate. Obi. — **cleona** *Cr.*, the first described race from the Southern Moluccas, bears a very small yellow oblong spot at the apex of the cell of the forewing. All the vitreous patches of the ♂ dull yellow, those of the ♀ light yellow,

tigrana. commonly with greenish sheen. Amboina, Ceram, Uliasser. — **tigrana** *subsp. nov.* inhabits Halmaheira and Batjan. ♂ essentially darker than that of *cleona*, with narrower yellow spots. ♀ of deep lemon-yellow colour. Cell of the forewing less dusted with black, which is especially noticeable beneath, and larger

lutescens. yellow and white submarginal spots on the forewing. — **lutescens** *Btlr.* is distinguished by greenish yellow, dull vitreous spots, which in the ♀ assume a buff tone. The black marginal area of the hindwing more extended than in *cleona*, the ultracellular patches smaller and hence more isolated. Buru. — Finally,

lucida. **lucida** *Fruhst.* (76 e) is the lightest extreme of the group; the vitreous spots of the ♂ yellowish green with the gloss of horn, whitish green in the ♀, which bears in addition a double row of pure white submarginal dots. Sula Mangoli, discovered by W. Doherty.

On **D. pumila** (76 e) Moore has founded the untenable genus *Phirdana*. This charming species

pumila. exclusively inhabits New Caledonia and the New Hebrides, where it is divided into two races: **pumila** *Bdv.*, from New Caledonia, with entirely yellow diaphanous cell on the forewing, a large, very transparent discal area on both wings and fine yellow vein-stripes on the hindwing. Under surface of the hindwing with two rows of extremely small blue-white submarginal dots and a white crescent at the costal margin. Abdomen

hebridesia. beneath white, laterally red-brown and dorsally black. — **hebridesia** *Btlr.* is the race from the New Hebrides, described from Aneitum, which is unknown to me in nature.

philo. **D. philo** *Gr.-Sm.* An isolated species, of which only one ♀ is known, which its author compares to *phyle Fldr.* from the Philippines, but places in the *Ravadebra*-Group. Judging from the figure it is a distinct species of medium size, scheme of markings as in *albata sulewattan Fruhst.* (78 d), only paler, more yellowish instead of green, and with smaller spots. Sumbawa.

D. vitrina, on which Moore based the „genus *Ashtipa*", exclusively inhabits the Philippines, and is probably, except for a few *Ideopsis*, the most thinly scaled of the Danaids. Cell of the forewing vitreous, and also the rest of the upper surface of the wing, which is only narrowly margined with black. *vitrina* is divided into several not very sharply differentiated island races, of which, however, I have only

vitrina two before me. — **vitrina** *Fldr.*, not rare on Luzon, bears large white spots in the distal margin of the

odrysia. forewing, and particularly in the ♀ beneath the hindwing has a white sheen. — **odrysia** *subsp. nov.*, with blue-white vitreous areas, narrower and more pointed ultracellular patches on the hindwing, which especially beneath are divided by broad black veins. Hindwing with blue-white sheen, submarginal dots very small. Island of Samar.

D. schenki is a magnificent species, sexually dimorphic, distributed from New Guinea to the Solomons and westwards to Wetter. Concerning its habits it is only known that the species is not rare and according to Kühn flies in bamboo-thickets. But it doubtless replaces *aspasia* and *cleona* in the Papuan

distrata. region, while wanting in Australia. — **distrata** *subsp. nov.* (76 d) is the most westerly race and especially in the ♀ is characterized by large, pure white and complete rows of submarginal dots, which are still more distinct on the under surface than above. Moreover, the whitish area in the cell of the forewing is more

gloriola. developed than in more easterly forms of *schenki*. Wetter, Kisser. — **gloriola** *Btlr.* (described from Aru) I have not seen in nature, but according to Butler it bears narrower whitish subapical streaks on the

citrina. forewing than **citrina** *Fldr.*, described from Key. The specimens I have received of this are smaller than

periphas. *distrata*-♂♂ and bear beneath correspondingly reduced white submarginal dots. — **periphas** *subsp. nov.* is the race from the whole main island of New Guinea and the Louisiade Archipelago, whose ♂♂ show no distinct black connecting streak along the upper median between the spot at the apex of the cell and the

distal border of the forewing. ♀ very similar to that of *distrata*, but with reduced vitreous cell-stripe and almost always without a trace of white submarginal dots on the upperside of the hindwing. On the under surface particularly the base of the hindwing is scarcely appreciably tinged with yellow. Milne Bay, German and Dutch New Guinea, nowhere rare. — **schenki** *Koch*, whose name-type came from New Georgia, does not vary materially on the Solomons. ♂ more greenish instead of deep yellow, ♀ on both surfaces with paler disc than the ♀ of *periphas*, but with distinct series of white submarginal dots. *schenki.*

D. clinias *Gr.-Sm.*, of which only one ♂ is known, is perhaps a distinct species, it is essentially larger than *schenki*, with a short yellow cell-streak on the forewing and much reduced ultracellular patches on the hindwing. The submarginal spots of both wings above deep yellow, relatively large. New Mecklenburg. *clinias.*

D. timorica *Gr.-Sm.* is a charming species from Timor, of which only one ♀ is yet recorded. Cell of the forewing entirely black, markings otherwise as in *distrata*, all the hyaline patches deep and dull yellow, both wings with small submarginal dots, which on the hindwing are always placed in pairs at the veins. In size not much surpassing *pumila*. *timorica.*

D. kirbyi *Gr.-Sm.* is hitherto only known from New Guinea; it was discovered at the Sattelberg, but has been recently sent to me also from the Hansemann Mountain behind Friedrich-Wilhelmshafen. Two colour-forms of the ♂ occur, of which it is still unknown whether they must be regarded as seasonal or local. — **decolorata** *Fruhst.* (76 d) comes from the Hansemann Mauntain and has the basal areas on the upper surface entirely pale greenish white, without the yellowish tinge which the figure incorrectly shows. This yellow basal colouring, even more pronounced and extended than on figure 2, is indeed peculiar to *kirbyi*. The ♀ has white, pale median areas on both wings and differs from the very similar *schenki*-♀♀ in the broader, more brown-black margins and the more distinct submarginal dots on both wings. *kirbyi.* *decolorata.*

D. rotundata *Gr.-Sm.* recalls a *Pareronia* in the arrangement of the blue-green intraneural areas. The cell-streak of the rounded forewing long and narrow, cell of the hindwing without black margining, marginal area of the forewing with large round submarginal spots, hindwing without. Under surface as above, with 2 parallel rows of submarginal dots, of which those of the inner series are larger. Very rare, only a few examples known. New Mecklenburg, New Pomerania. *rotundata.*

P. garamantis *Godm. & Salv.*, similar to the preceding, but with much more elongate forewing and sharply angled instead of rounded hindwing. The blue-white markings arranged as in *rotundata* except that the cell-spot of the forewing is shorter and the cell of the hindwing broadly filled up with black, so that only a narrow stripe runs through its middle. All the streaks of the hindwing narrower, and in contrast to *rotundata* the wing bears also above a submarginal row of strong white spots. Apparently rare. Guadalcanar, Solomon Islands. *garamantis.*

D. melusine *Gr.-Sm.* was discovered on the Sattelberg in German New Guinea and has also been sent to me from the Gelu Mountain behind Friedrich-Wilhelmshafen, but appears to be everywhere rare and not to occur below 500 m. The black margining of both wings is much more extended, so that there is no cell-stripe on the forewing; the circumcellular spots of the hindwing are reduced, and the upper submarginal spots are absent; under surface of the forewing black with blue-white intraneural areas, that of the hindwing black-brown with yellowish median spots and two rows of submarginal dots becoming obsolete towards the anal angle. Abdomen black-brown with lateral white dots. Palpi black with white lateral stripes. ♀ only a little larger than the ♂, with more rounded wings. *melusine.*

Group Parantica *Moore* (1880).

A somewhat heterogeneous group, whose structural diversity has escaped Moore, for only one of its components, „*aglea*", corresponds to the „generic diagnosis", i. e. has a subcostal vein of the forewing joining the costa. Third median vein of the hindwing with a broad patch of androconia. Valve of *eryx* basally broad, then suddenly narrowed, produced into a long sharp point. Uncus consisting of two very long, narrow, delicate appendages. Larva with 2 pairs of tentacles.

D. eryx, the type of which probably came from Siam, from whence Fabricius obtained many species, inhabits the whole of Further India from Burma to Cochin China and was very common in Siam, where it reposes confidingly on the flowers in the temple-gardens of Bangkok. Several island races inhabit the Macromalayan districts. — **eryx** *F.* (= agleoides *Fldr.*) (77 b) extends westwards to the Nicobars, and is one of the commonest butterflies in North-Eastern Sumatra; it exclusively inhabits the plains and appears never to ascend even to the spurs of the mountains. The ♀ has rounded forewing, somewhat broader and whitish grey stripes. — In western Sumatra occurs a form with much narrowed cell-stripe and more delicate submarginal spots on the forewing and essentially smaller submarginal dots on the hindwing: **maenius** *Fruhst.* — A nearly allied race is found in West Java, with shorter, broader and whitish instead of grey-green intraneural areas; **furius** *Fruhst.*, which is apparently very local and probably only occurs *eryx.* *maenius.* *furius.*

borneensis. near Batavia. In the course of 20 years I have only received 3 examples. — **borneensis** *Stgr.* is a much darkened form from southern Borneo with very thin greenish subapical streaks and indistinct cell-stripes. South-East Borneo, Pontianak. — In North Borneo there occur ♂♂ in which the forewing is almost *terilus.* entirely blackened and the hindwing also shows only 3 basal lines and minute submarginal dots: **terilus** *Fruhst.* — The change which *eryx* undergoes on Nias may be regarded as an instance of the melanism of *erycina.* the satellite islands; here occurs **erycina** *Fruhst.* (77 b), in which in both sexes the cell-stripes of the forewing are scarcely visible and only the postdiscal and submarginal patches remain distinct. The under surface of both wings is deep brown-black instead of predominantly grey as in the other *eryx*-races.

D. aglea is a predominantly continental species, which sends out branches to Ceylon and Formosa and naturally extends onto a number of the neighbouring small islands. It is on *aglea* that Moore based the genus *Parantica,* which strictly speaking embraces only this species and *melanoleuca Moore,* for only in these two the first subcostal vein is united with the costa on the forewing. This anastomosis does not reappear even in *eryx,* but is probably to be regarded as only a character of secondary importance, which, although in *aglea* it remains constant, yet in other species, e. g. Euploeas, may occur as an aberration. *aglea* forms at the same time a transition to the group *Chittira* in having the submedian of the hindwing *aglea.* thickened in the subanal part. — **aglea** *Cr.* (=ceylonica *Fldr.*) is known from Ceylon and South India, extends northwards on the west of the Indian peninsula as far as Bombay and is regarded as the commonest butterfly of Ceylon. Forewing relatively narrow; apex strongly produced, cell of the forewing much darkened in the anterior part, especially in the ♂♂, hindwing not essentially different from that of the figured *maghaba* (77 b). Larva on Asclepiadeae, with 2 pairs of tentacles, of which the anterior pair are long, the posterior much shorter; colour reddish, with chrome-yellow and white spots, head and legs black. *grammica.* Pupa green, barrel-shaped, with central constriction and black and golden dots. — **grammica** *Bdv.* (= melanoides *Moore*), larger, wings more rounded than in *aglea,* with transparent cell finely striped with black and long, broad subapical streaks on the forewing. Inhabits the rainy parts of the Himalayas and is very common in Sikkim and Assam, where it occurs up to 2000 m., and becomes extremely rare at Simla and *phormion.* the dry western Himalayas. — **phormion** *Fruhst.* is a smaller local form, somewhat more broadly margined with black and consequently with all the vitreous subapical and submarginal spots narrower. Tonkin, Annam, probably also Tenasserim and the Mergui Archipelago. Common even in the gardens at Haiphong. *maghaba.* — Finally, **maghaba** *Fruhst.* (77 b) is a very large and melanotic race, likewise with the streaks of the forewing reduced and the circumcellular patches of the hindwing narrowed. Ground-colour of all the vitreous patches darker, the black postmedian area of the hindwing beneath more extended than in Sikkim and Assam ♂♀. Not rare in Formosa, where it flies all the year round.

melanoleuca. **D. melanoleuca** *Moore* without doubt represents the preceding species on the Andamans; it has the same neuration and arrangement of the spots, but is still more transparent than *aglea,* so that Moore erroneously placed it in *Ashtipa,* a group to which *vitrina Fldr.* belongs. The black distal border of both wings narrower than in *aglea,* hence the ultracellular patches of the hindwing more extended. The white subapical band of the forewing more compact, especially beneath, its black bordering more extended than in *aglea.* Inhabits the Andamans, where it flies all the year round. Bingham has apparently received it also from the Nicobars.

Group Chittira *Moore* (1880).

(*Caduga, Mangalisa, Lintorata Moore* 1883. *Badacara Moore* 1890. *Chlorochopsis Rothsch.* 1892.) The essential structure exactly as in *Parantica,* so that the group is only distinguishable by ♂-characters without generic value. Submedian and inner marginal veins before the margin widened and grooved somewhat like the eye of a needle, swollen. Submedian surrounded by a broad and subcostal by a narrow patch of androconia, the extent of which is very variable. Larva as in the preceding group with 2 pairs of somewhat shorter and more bristle-shaped tentacles. Uncus basally thickened so as to form a small knot, distally ending in a fine hairy point, forming a contour which recalls the palpi of *Tanaecia.* Valve broad, of simple build, almost triangular in shape, with chitinous, slightly flattened tip. The species of this group are preeminently inhabitants of the mountains.

fumata. **D. fumata** *Btlr.* (= taprobana *Fldr.*) (77 a), hitherto only known from Ceylon, where it prefers altitudes of 1500—1800 m., but descends to 1000 m. It differs from all other Danaids in the broad marginal area, above black and dark grey-brown, which only leaves some subapical stripes, a cell-streak and a submedian stripe on the forewing and the cell of the hindwing; ♀ larger than the ♂, with more rounded wings. Abdomen above brown, beneath whitish grey. *fumata* flies during the whole year, and is locally not rare.

phyle. **D. phyle** *Fldr.* is so similar to it in the scheme of markings that it is best considered here, although geographically far removed. Forewing as in *fumata,* but with larger hyaline intramedian patch and more strongly expressed submarginal patches on the forewing. Hindwing with a complete series of vitreous, greenish grey circumcellular spots, approaching in shape those of *nilgiriensis* (77 b). The submarginal row of dots on the hindwing distinctly present also at the hinder angle. On the under surface in the light brown

ground-colour and the slightly red-brown cell of the forewing it forms a transition from *taprobana* to *albata*. Abdomen above grey-brown, beneath white-grey. Hitherto only observed on Luzon, occurring there in the alpine districts of the north-west and at elevations of 600—1550 m.

D. albata was only known from Java until 1896, when it was discovered by me in a large race on Celebes and has recently been sent to me also from the volcano of Singalang in West Sumatra, so that there are now four geographical races known. — **adustata** *Fruhst.* ♀ somewhat lighter, more transparent, *adustata.* the vitreous areas more glossy than in *albata*. The three subapical bands of the forewing somewhat narrower, separated by broader black veins, the anterior patches between the median veins and also the submarginal spots more distinct, the latter purer white. Under surface and distal border of the hindwing black with a rather distinct red-brown tinge, cell with a forked brown longitudinal stripe, which is absent in *albata*. West Sumatra, but evidently very local, only 2 ♀♀ from 2000 m. — **albata** *Zinck.* is a character- *albata.* istic Javan butterfly, which at once attracts the attention of the traveller when he ascends above elevations of 1200 m.; it flies in almost any weather and seems quite at ease even amid the sulphureous smoke of the volcanoes, occurring up to about 8000 ft. on Mts. Tjikorai and Gedé. Somewhat smaller than *sulewattan* (78 d), but bears broader, lighter subapical bands on the forewing. Under surface of both wings earth-colour. West Java, flying all the year round. — **gilva** *subsp. nov.* is the East Javan local form, *gilva.* principally observed by me in the Tengger Mountains, smaller than *albata* and giving quite the impression of a dry-season form; under surface smoke-brown, paler than in *albata* and the cell of the hindwing almost always darkened by a more or less extended grey-brown tinge. — **sulewattan** *Fruhst.* (78 d) inhabits the *sulewattan.* Peak of Bonthain and flies about wildly at elevations of 5000—6000 ft. over the evergreen brushwood which borders some of the grassy plots levelled by the hand of man. Forewing with projecting apex; ground-colour somewhat lighter brown than in *albata*, the vitreous areas more clouded, more brown instead of whitish green. Subapical strigae of the forewing materially narrowed; the distal row of submarginal dots on the hindwing is absent beneath; the dull transparent areas grey-green, the marginal region light brown; abdomen beneath yellowish, instead of white as in *albata*. *sulewattan* is no doubt a faunistic legacy of the land-connection with Java and zoogeographically of the highest interest, so much the more as it flies in company with *Pyrameis dejeani*, *Ilerda epicles* and a race of *Pap. sarpedon*, which likewise recall the former connection with Macromalayana. — **kuekenthali** *Pagenst.* is the North Celeban representative of *kuekenthali.* *albata*, approximating in size to *gilva*, being essentially smaller than *sulewattan*; the subapical stripes even narrower, the transparent areas of both wings greenish yellow. Under surface as in *sulewattan*, washed-out brown. Abdomen above black, beneath yellowish. Discovered by Professor Kükenthal on the Rurukan at 4000 ft., later also taken by Hose near Tondano.

D. weiskei *Rothsch.* represents the *albata*-group on New Guinea, where it is likewise alpine, but is *weiskei.* smaller. The sexual spot of the hindwing is especially sharply marked. Forewing without transparent cell-stripe and with rounded instead of elongate subapical spots, hindwing with *albata*-pattern, of greenish white colour. Under surface: forewing black, hindwing umber-brown. Aroa River, British New Guinea, only 1 ♂ collected, named after its discoverer.

With **D. nilgiriensis** *Moore* (77 b) begins a series of species which betray their relationship to the *nilgiriensis.* *Parantica*- and *Radena*-type by the narrow intraneural areas. Under surface of *nilgiriensis* pale earth-brown, all the transparent areas greenish. Abdomen beneath brown. Apparently nowhere rare in the Nilgiris, but not found below 2000 ft. Principal time of flight April and May.

D. luzonensis replaces *nilgiriensis* in Micromalayana, on Borneo and the Philippines. The small Sunda Islands, which are at the greatest distance from Anterior India, produce the races most closely approaching *nilgiriensis* in the coloration, whilst the neighbouring countries (Java, Borneo) produce the most specialized. Strange to say, no branches are as yet known from the Malay Peninsula, Further India and Sumatra, so the distribution of the species must be called an entirely discontinuous one. — **luzon-** *luzonensis.* **ensis** *Fldr.* is an extremely constant race, although it occurs on all the Philippine Islands from Luzon to Mindanao and even Palawan, but appears to be nowhere common. The intraneural areas are almost as broad again as in **præmacaristus** *Fruhst.* (78 c), in which also the underside of the abdomen, which is *præmacaristus.* almost pure white in *luzonensis*, is grey, there being a distinct forked marking in the cell of the hindwing. North Borneo, very rare, hitherto only one ♂ described from coll. Fruhstorfer. — **larissa** *Fldr.*, *larissa.* on the other hand, is a subspecies ascending on the whole of Java to about 2000 ft., nowhere common, but also nowhere scarce. Abdomen beneath red-brown, otherwise much more recalling the Philippine race in the wing-pattern and bearing even more distinct and complete rows of submarginal dots on the hindwing. — **panaitius** *subsp. nov.* is an extremely rare race on Lombok at elevations of about 700 m., with *panaitius.* the abdomen grey beneath, the cell of the forewing completely blackened and the vitreous areas of the hindwing even less developed than in *præmacaristus*. Under surface of the hindwing brown-black, the cell and discal strigae lightly powdered with reddish. — **orientis** *Doh.*, described from a ♂ from Sumba and of *orientis.* which I have before me a somewhat different form from Sumbawa, is above deceptively like *nilgiriensis*

in the colouring, with dull grey-green interneural areas. Under surface paler than in *panaïtius*. Abdomen ventrally almost pure white.

melaneus. **D. melaneus** is a mainly continental species, whose races have hitherto not been sufficiently studied, so that several long-known forms still require naming. The name-type **melaneus** *Cr.* probably comes from southern China and is most likely identical with examples from Tonkin. These again, in the long-produced *szetchuanus.* forewing and the larger size, approximate much more to **szetchuanus** *Fruhst.* (78 c), which is still darker above, than to the Indian continental branch, which Dr. SEITZ has figured vol. I, pl. 28 d, and whose rounded wings contrast so distinctly with the pointed ones of *szetchuanus*. The latter is perhaps only a dry-season form, with red-brown instead of black postdiscal areas on the hindwing beneath, from the mountains of China, especially from the Omi-Shan, where according to LEECH it occurs commonly. In Tonkin I found it exclusively in the Manson Mountains at elevations of about 1000 m. and only in the *plataniston.* month of April. — **plataniston** *nom. nov.* is the round-winged race so common in the Himalayas which stands in all collections as *melaneus*. It is beneath more uniform and lighter red-brown. In Sikkim it ascends from the valleys to about 2000 m., and is very common from March to December. Examples of *neopatra.* the dry-season form, **neopatra** *form. nov.*, are essentially smaller, beneath almost entirely light red with pure white submarginal dots on both wings. *plataniston* also occurs singly in Tenasserim and Siam. — *sinopion.* As **sinopion** *subsp. nov.* we introduce the apparently very rare race of the Malay Peninsula, characterized by narrower vitreous areas and particularly by the almost entirely black ground-colour of both wings be- *swinhoei.* neath, which only show slight traces of a red-brown tinge. — **swinhoei** *Moore* is a well defined race from Formosa, of smaller size, with darker red-brown abdomen, somewhat narrower costal patches on the forewing and very broad dark red-brown marginal area on the hindwing beneath, the ultracellular patches *pseudo-melaneus.* being much restricted. Flies March to August, not rare at Lake Lehiku. — Finally, **pseudomelaneus** *Moore* is a highly specialized race which I only observed in western Java, and there only at the volcano Gedé at elevations of above 4000 ft. Forewing strongly falcate, the vitreous areas very transparent, shiny, clear, hindwing with a two-branched cell-streak, which is wanting in all the other subspecies of *melaneus*. Abdomen above light red-brown, beneath grey-white. Colour of the under surface of the wings, as in *sinopion*, with the admixture of red-brown very slight.

banksi. **D. banksi** represents *melaneus* on Sumatra and Nias, but is so modified in shape and colour that it is probably a distinct species. **banksi** *Moore* inhabits both the plains and the foot-hills, but according to MARTIN examples from the plains are paler and poorer in colour than those of the mountains. Sub- *funeralis.* median area of the forewing divided by a broad black streak, which is not the case in any form of *melaneus*, cell of the hindwing likewise with strong streak. Abdomen dark red-brown. — **funeralis** *Btlr.* has moreover, the cell of the forewing blackened, narrow vitreous interneural areas and a ventrally yellowish abdomen. Nias, apparently very rare.

crowleyi. **D. crowleyi** *Jen.-Weir.* is a giant form from northern Borneo, whose ♂♂ equal the largest ♀♀ from Tonkin with the forewing 55 mm. in length, but show the rounded wing-contour of *banksi* and have likewise in common with this the broad transverse stripes in the submedian area below the cells of both wings. Abdomen, however, ventrally white, with grey rings and dark grey dorsal line. Upper and under surface of both wings almost uniformly coloured, slightly tinged with red-brown, anterior part of the cell of the forewing black, the posterior part narrowly vitreous, intraneural areas relatively narrow considering the size of the butterfly, the submarginal dots of the hindwing very small, grey-white. This magnificent species inhabits Mt. Kina Balu in North Borneo and is rare.

menadensis. **D. menadensis** *Moore* (78 d) replaces *melaneus* on Celebes; the different colour of its stripes (yellow instead of whitish or greenish) has already won for it two generic names, namely *Lintorata Moore*, who even classified it with the African Danaids, and *Chlorochopsis Rothsch.* The species is rare both in northern and southern Celebes, exclusively inhabits the plains and is probably overlooked on account of its resemblance to the common *D. luciplena Fruhst.*, although it has a more rapid flight than this and keeps somewhat further from the ground. Most examples are somewhat lighter than the figure and brilliant yellow, especially beneath. ♀ only a little larger, wings more rounded than in the ♂, with paler, scarcely appreciably broader stripes and spots.

D. sita, better known under the name *tytia*, has of all the Danaids the most extended androconial patches on the hindwing, which are thickest at the submedian, proximally and distally extend over the inner-marginal vein and the lower median and are very variable in shape and extent. *sita* is a mountain species, only beyond the tropics descending also into the plains; it is long-lived and a tenacious flier and keeps higher above the earth than other *Danaida*. — Larva described in vol. I, p. 77, on Marsdenia roylei, one of the Asclepiadeae. From eggs laid in September the butterflies emerge in the following April. In Hong-Kong the first butterflies appear at the beginning of February. In the North-West Himalayas four broods have been observed, of which the first appears in April, the fourth in October. The species inhabits elevations of 2—3000 m., extending northwards to the island of Askold, and on Tsushima I observed ♀♀

still flying about vigorously at the end of September. — **sita** *Koll.*, known from the western Himalayas and Kashmir, is a form with pale red-brown margins, which occurs at wooded places occasionally in large numbers and ascends to 10,000 ft. — **tytia** *Gray*, a darker race with thick red cell-streak on the hindwing, which gradually disappears in examples from the eastern Himalayas, is always absent in the dry-season form from Assam and apparently does not occur at all in ♂♀ from Tenasserim. Such examples have been described as **tira** *Fruhst.* — **ethologa** *Swinh.* is a darkened geographical race from the Malay Peninsula with dark brown margins to the wings and shorter subapical patches on the forewing, of which only a few examples have hitherto been found. — **loochooana** *Moore*, a specially large subspecies, with the margins more chestnut-brown, occurring on Formosa and the Loo Choo Islands, is distinguished like **niphonica** *Moore* (vol. I, pl. 28 e ♀) by having the abdomen dark grey above and white beneath from the red-bodied *tytia*, which is only ringed with white beneath. The genitalia are described in the diagnosis of the group. — **tityoides** *Hag.* (78 d) is an essentially modified race, which might almost rank as a species. The anterior half of the cell of the forewing blackened, the subapical stripes narrower, hindwing above paler red-brown, the discal patches obsolete, hence the red entering the cell. ♀ with rounded forewing. Everywhere in the mountains of Sumatra at elevations of 1000 m., but nowhere common.

sita. *tytia.* *tira.* *ethologa.* *loochooana.* *niphonica.* *tityoides.*

Group Radena.

In neuration this group approaches *Ideopsis*, with which *Radena* has also in common the slight development of the androconia, which are scarcely visible to the naked eye and only accompany the submedian of the hindwing. According to my preparations of the neuration, the first subcostal vein is coincident with the costal, as in *Ideopsis*, a condition which is repeated as an aberration in *Parantica aglea*. But *Radena* is removed from *Parantica* and *Chittira* by the very long lower discocellular of the hindwing, which is obliquely directed proximad, whilst the longer antennae connect the group with *Ideopsis*, to which the shape of the valve also forms a transition. Uncus cylindrical, relatively short, distally rounded. Valve unusually broad, distally sharply truncate, with a beak-shaped tip, which, however, is broader basally than in *Ideopsis*. Saccus larger than in the other Danaids and Euploeas, testicle-shaped. Anal pencil according to Doherty shorter than in all the other Danaids, its hairs white at the base, grey distally. Larva with two pairs of tentacles as in *Parantica* and *Tirumala*. Pupa trunk-shaped, green with black dots.

D. similis is one of the commonest butterflies of the East Indies and is distributed from the Loo Choo Islands to Palawan and from Ceylon to Sumbawa. It is always found near human settlements, flutters heavily over flowers and grasses, is gregarious like most Danaids and emits a repulsive mouse-like smell, which emanates from the body. — **similis** *L.* is the name-typical subspecies, described from South China, and very common in Hong-Kong and Formosa. On the continent *similis* inhabits the whole of Further India without varying locally. As **aventina** *Cr.* (78 c) an aberration has been described with the postcellular spots of the forewing rounded instead of acutely wedge-shaped. — **persimilis** *Moore* belongs to the dry season and is known from Siam, where it occurs in enormous numbers near Bangkok; it is smaller than *aventina* and has correspondingly narrower grey-green interneural areas. As **hyria** *form. nov.* we designate an aberration of like habitus to *aventina*, but with the vitreous areas on both wings almost twice as broad and whitish instead of green. Some of the subapical patches are confluent. Occurs in Annam and Tonkin during the rainy season together with the type-form, but is very rare. — On the Loo Choo Islands Ishigaki and Okinawa there is a race with light green stripes, especially beneath, of almost white-green colour and with the submarginal patches much enlarged: **tragasa** *subsp. nov.* — The form from the Malay Peninsula is well known as **vulgaris** *Btlr.*, and approximates to **macrina** *Fruhst.* (78 b), from West Sumatra, which is distinguished from *vulgaris* by having the entire colouring darker and the vitreous patches reduced. Flies all the year round, one brood following another. Only in February and March, when an interruption occurs in the regular rains, worn specimens are met with, so that Martin assumes that wet weather is essential to its emergence. — **vulgaroides** *Fruhst.* is very common on Java, especially in the east, at elevations of 300—500 m. The marginal and subapical dots and strigae smaller, narrower and shorter than in *macrina*. The apical spots and the basal streak in the cell of the forewing more reduced, also the postcellular patches smaller. Under surface of the wings darker, the bands brownish instead of whitish. — **megaroides** *Fruhst.*, which is the most melanotic of the races hitherto known, inhabits Nias; smaller than *macrina*, but has in proportion to its size larger white submarginal dots on the forewing, whilst the whitish bands of the hindwing are strongly reduced. The small ultracellular wedge-spots of the forewing are shorter than in *macrina* and also in **macra** *Doh.*, from Engano, which latter differs both from Javan and Nias examples in the darker green stripes and dots, but especially in the projecting apical part of the forewing. Borneo examples and also ♂♀ from the Natuna Islands are scarcely distinguishable from *megaroides* from Nias and to some extent form a transition from Nias specimens to *vulgaroides* from Java. The name **interposita** *subsp. nov.* might be introduced for them. — Strikingly different from Macromalayan *similis* is the form inhabiting Ceylon, which is known as **exprompta** *Btlr.* (78 b); it was formerly very common at Colombo, but according to recent records has now disappeared from there. ♀ even more broadly striped and lighter than the ♂, with the forewing more rounded. — **nicobarica** *Wood-Mas.* so strongly recalls *juventa* that for years I had it placed in my collection as *juventa subsp.*

similis. *aventina.* *persimilis.* *hyria.* *tragasa.* *vulgaris.* *macrina.* *vulgaroides.* *megaroides.* *macra.* *interposita.* *exprompta.* *nicobarica.*

Forewing with very broad cell-streak, the subapical patches joined together and rounded bluish white intramedian areas. Cell-streak and discal spots of the hindwing smaller than those of *exprompta*. Nicobars, apparently very rare. — **palawana** *Stgr.* (78 c) closely resembles *Papilio macareus* in consequence of the much widened strigae and submarginal patches of both wings. Cell-streak of the hindwing distinct, distally forked, but not so strongly developed as in the preceding races. Palawan, January, not rare. — **sumbawana** *Fruhst.* (77 b), of which a ♀ is figured, erroneously described on the plate as a ♂, shows still more extended white areas and patches, on the other hand the cell-streak of the hindwing is much reduced. The ♂♂ are even lighter than the ♀♀, with the apex more produced. Sumbawa, rare. — **lesora** *subsp. nov.* is distinguished by a broad black marginal area, smaller wedge-shaped subapical spots and more isolated transcellular patches on the forewing. Under surface of both wings traversed by broad black veins, the fork in the cell more pronounced. Flores, likewise rare, and so similar to *juventa* that I have only now learnt to place it in the *similis*-group. — Finally, **kambera** *Doh.* is clearly the product of an island with a long dry season; its forewing may be described as white, with narrow black margins. The cell-streak of the hindwing is rudimentary, but the principal character of the form is the broad white subapical areas of the forewing. *kambera* is almost a distinct species and on account of its resemblance to *juventa* I formerly referred it as well as the preceding form to that species. But the valve is exactly as in *similis*, which, however, can scarcely be distinguished from the valve of *juventa*. Sumba, apparently very rare.

palawana. *sumbawana.* *lesora.* *kambera.*

D. oberthueri *Doh.* is an entirely isolated species, only occurring on Sumba, where it appears to replace the common *similis*. But apart from the shape it has scarcely any resemblance to it. Ground-colour deep black, in the ♀♀ changing on the hindwing into a light brown. Forewing otherwise as in *similis*, but without marginal patches and with the ultracellular series of hyaline spots broadened into a conspicuous band, cell of the hindwing without fork, the transcellular patches and submedian stripes more than twice as large as in *similis*. Under surface of the forewing black-brown, that of the hindwing washed-out grey-brown.

oberthueri.

D. juventa, like *melissa* and *affinis*, is one of those Danaids which occur throughout the tropics of the East, and is even more susceptible to climatic influences than these, with the result that it splits up into an almost unprecedented number of geographical races. It is interesting that *juventa* nowhere extends to the continent and is hence a typical island species. Its occurrence in Malacca and Perak has indeed been reported, but it is apparently still rare, having perhaps only migrated there quite recently, and moreover the southern part of the Malay Peninsula has so pronounced an insular character and such a thoroughly maritime climate that this coast species would be quite in its element there. In its horizontal distribution *juventa*, like *melissa*, is wanting on Sumatra, also it does not seem to occur on Nias and the Batu Islands, but it is found on Engano, which it may probably have reached from Java. — Larva of the various island races apparently differing; black on Java, Semper figures it entirely white from Manila. Legs on Java black, on the Philippines red. Larval stages on the Philippines 14—16 days, pupal stage 9—10. Semper believes he has observed seasonal forms. On Java the species flies all the year round, but only in January during the heaviest rains occurs in enormous numbers and probably does not ascend beyond 600 m. above sea-level. Valve as described in the diagnosis of *Radena*, scarcely distinguishable from that of *similis*. — **juventa** *Cr.*, the first described subspecies, inhabits Java and Bali; like all the allied races it has the forewing more rounded in the ♀ than in the ♂, differing from the figured *mincia Fruhst.* (78 b) in the shorter vitreous yellow-white spots at the apex of the cell and between the medians of the forewing. — **mincia** inhabits the island of Bawean, which though so near to Java is noted for its highly differentiated endemic forms, which sometimes might almost rank as species and hitherto in most cases have been introduced as such. As in *rita* of the *Parantica*-group *mincia* is also characterized by the enlarged and still more transparent vitreous spots of both wings. — **longa** *Doh.* on the contrary offers an excellent example of island melanism, with its sharply defined, small-dotted marginal areas and thickly black veins, which only leave narrow greenish white vitreous stripes; in this *longa* recalls *tontoliensis* (78 a) rather than *juventa*. Very common on Engano. Principal time of flight April. — If large series of *juventa* from Java and from Lombok are placed side by side, it is seen that the Lombok examples, **phana** *Fruhst.*, are larger and bear lighter and more extended hyaline patches, but a darker, black distal border to the wings. This marginal border has smaller white dots than in the Javan race. The white comma-shaped streak between the subcostal veins of the forewing is longer, the ultracellular and cellular patches of the forewing are larger than in *juventa*. *phana* occurs on Lombok up to elevations of 2000 ft. and is not rare even in the village gardens. — **stictica** *Fruhst.* is larger than *phana*, the black transverse streak before the cell of the forewing begins to disappear, so that the cell may be described as transparent throughout. All the median areas on both wings very large, the submarginal dots, especially in the ♀♀, almost always united. Sumbawa, not rare. — **kallatia** *Fruhst.*, from Kalao, quite suggests a dry-season form, perhaps a result of the long almost rainless period to which the butterflies of Kalao are exposed. All the hyaline patches purer white but less transparent than in *stictica*, submarginal patches very distinct, but both rows of subapical spots more reduced than in Sumbawa ♂♀, cell of the forewing

juventa. *mincia.* *longa.* *phana.* *stictica.* *kallatia.*

with broad transverse stripe, that of the hindwing of the ♀♀ without fork, with only the vestiges of a fine line. — **lycosura** *subsp. nov.* is the race from the small island of Bonerate; it singularly is somewhat larger than *kallatia*, but at the same time has smaller and hence more isolated postdiscal patches on the hindwing and more delicate, small subapical wedge-spots on the forewing. — **sitah** *Fruhst.*, from the Natuna Islands, is distinguished by the narrower and longer forewing, in which it differs from *juventa* and from the following races. *sitah* is a melanotic island form, with the hyaline spots reduced and the black colour more extended. All the patches are of a more greenish than yellowish white colour. The under surface of the wings is more black than brown, all the ultracellular spots shorter and narrower. The submarginal dots are however more extended, larger and more distinct. — **kinitis** *Fruhst.* North Borneo produces a further race, which approaches *manillana Moore* from Luzon. 2 ♀♀ and 2 ♂♂ in my collection differ from *juventa* from Java in the larger whitish patches on both wings, the intermedian spots especially are much broadened. The forewing is broader and shorter than in *sitah*; all the subapical streaks longer. Sandakan and neighbourhood of Labuan, North Borneo, and probably also Palawan. — **goria** *Fruhst.*, from Bazilan, is intermediate between *kinitis* and *manillana*; as in *sitah* the hyaline patches are of a more blue-green than whitish colour. The black distal border of both wings is much darker than in the allied races, the submarginal white dots smaller than in *kinitis*. The ultracellular patches are shorter, neither round, as in *juventa*, nor almost quadrate, as in *kinitis*, but distally pointed. The transcellular spots of the hindwing are very small, scarcely 1/3 as large as in *manillana* and hardly more than half as large as in *kinitis*. Bazilan, near Mindanao. — **galaecia** *subsp. nov.* is the antithesis of *goria*, very small, transparently white, with the transcellular spots on both wings sharply defined distally, more quadrate than rounded and much more extended than in *goria*, restricting the black distal border. Locality unknown, probably Mindoro or islands of the Negros Group. — **manillana** *Moore* is the very common race from Luzon, which SEMPER assumes to be seasonally variable. Although the postdiscal patches of the hindwing are well developed, they are distally pointed, scarcely half as broad as in *galaecia*. Larva on a climbing plant, legs carmine, and dorsal colouring whitish. — **luzonica** *Moore* according to SEMPER only occurs on the Babuyanes to the north of Luzon; but in conformity with the laws of the Zoological Society the misleading name has to be retained. *luzonica* is a highly specialized island form, of typical melanotic colouring, very large, with relatively small, isolated white rounded spots on the forewing, which like the pointed postdiscal stripes of the hindwing are placed in a much widened black marginal area. The black stripes at the submedian of the forewing very long and broad. — **lirungensis** *Fruhst.* is a peculiar, large-spotted geographical form from the Talaut Islands to the north of Celebes, which forms a transition to the races of this island and the Moluccas. Forewing with projecting apex, but broader than in the Philippine races, the colour of the transparent areas greenish, submedian stripe of the forewing short but thick, cell likewise with strong but much abbreviated basal streak, postdiscal spots of the hindwing very small, remote from the cell-wall. Island of Lirung in the Talaut Group. — On the many-armed island of Celebes itself *juventa* is split up into three named races: **libussa** *Fruhst.* inhabits the most northerly part of Celebes, the Minahasa, and extends to the south-east as far as Kendari, and moreover onto the islands of Peling and Bangkai, apparently without varying. Margins of the wings black-brown with greenish white transparent areas and small dull white submarginal dots. As a rule smaller and the ♀ with larger spots than **tontoliensis** *Fruhst.* (77 a), which is only known to me from Toli-Toli in north-western Celebes. The cell-stripes of the forewing, and even the intramedian areas, are darkened, being covered with black-brown scales, the submarginal dots reduced, the whitish areas on the under surface likewise shaded. *tontoliensis* is probably a product of the rainy season, as is also indicated by the size of the specimens. Very common at the edge of the woods on the coast in November to December, where the butterfly is found on low flowering bushes, always in large numbers. — Essentially different is **tawaya** *Fruhst.*, which gives quite the impression of a dry-season form, and is based on a ♀ taken at that period. The cell-stripes and also the hyaline areas of both wings are broadened and like the submarginal spots purer white, an albinotic effect which is almost more noticeable on the under surface than above. Type from Tawaya, a place in the Bay of Donggala, in Central Celebes. — **ishma** *Btlr.*, figured by its author from Celebes examples, but whose locality is erroneously given as Gilolo, is the race which inhabits the south peninsula of the island and occurs in great abundance especially near Macassar and at the waterfall of Maros. *ishma* is next to *tawaya* the lightest form of the island, with almost pure white instead of greenish vitreous patches and very large cell-spots on the forewing. Moreover on the underside it is easy to distinguish from the eastern and northern Celebes subspecies by the more prominent double row of white submarginal dots on both wings. — **satellitica** *Fruhst.* inhabits Saleyer, where it is not rare from November to March; its small size, the reduced whitish patches and areas and broader black veins give the distinctive facies of a race inhabiting an outlying island. — **sophonisbe** *Fruhst.* closely approaches it in the small wing-expanse, but like *cleona lucida Fruhst.* bears glossy, very light vitreous areas and patches on both wings, which approximate to those of *tawaya* in shape. Submarginal dots pure white, especially those of the ♀♀. Sula Mangoli. — **sequana** *subsp. nov.* was discovered by H. KÜHN on Binongka, a small island to the east of Buton. In this all the transparent areas are even lighter, the butterflies are larger than those of the Sula Islands and Saleyer,

lycosura. *sitah.* *kinitis.* *goria.* *galaecia.* *manillana.* *luzonica.* *lirungensis.* *libussa.* *tontoliensis.* *tawaya.* *ishma.* *satellitica.* *sophonisbe.* *sequana.*

meganira. the marginal dots and especially the small costal and subapical wedge-spots essentially longer. — **meganira** *Godt.*, one of the commonest butterflies of the Southern Moluccas, differs from the preceding races in the more rounded shape of the wings, which is particularly noticeable in the ♀♀, and the rounded instead of rectangular or oblong postdiscal patches of the forewing, which in the corresponding races from the other Moluccas decrease or increase in size according to the greater or less extent of the black mar-

buruensis. ginal area. — **buruensis** *Holl.*, from Buru, is somewhat inferior in size to *meganira* and has the vitreous interneural areas just a little smaller and somewhat duller whitish than in examples from Amboina and

sobrina. Ceram. — **sobrina** *Bdv.*, whose locality its author erroneously gave as Buru, from whence he had himself already recorded *meganira*, is the race from the Northern Moluccas, a fact which Mons. Charles Oberthür has confirmed by comparison of the type. *curtisi Moore* (1883) is synonymous with *sobrina*. The white patches of the forewing rounded, the cell-streak thread-like, the two stripes at the submedian more elongated but narrower than in *eugenia* (77 a). Hindwing with distinct black fork in the cell, which in

ellida. *meganira* is only indicated. Halmaheira, Batjan, Ternate, everywhere very common. — **ellida** *Fruhst.* is geographically and morphologically an intermediate form between *meganira* from the Southern Moluccas and *sobrina*; it has pure white instead of greenish grey submarginal patches and the intramedian areas are only slightly more reduced than in *meganira*. The hindwing with its rudimentary cell-stripes and the almost white subbasal streaks agrees much more with *meganira* than with *sobrina*, which has the bands

ogylla. similar to those of *eugenia*. Obi, not rare. — **ogylla** *subsp. nov.* is a highly specialized race from the Aru Islands, which in colouring is about intermediate between *meganira* and *metaxa* (77 a), but bears only a very narrow cell-streak on the forewing and vestigial cell-stripe on the hindwing. Otherwise as in *meganira*, except that the wings are more rounded and the patches on the forewing greenish. Apparently rare. —

turneri. **turneri** *Btlr.* forms a transition from *sobrina* to *eugenia*. All the vitreous patches greenish as in *eugenia*; but the cell-streak of the forewing thread-like, in the ♀ completely absent and never joined to the spots before the apex of the cell. Dutch New Guinea, especially at Dorey and the foot of the Arfak Moun-

eugenia. tains. — In German New Guinea *turneri* is replaced by **eugenia** *Fruhst.* (77 a), a form which is not rare in the woods at the coast of Friedrich-Wilhelmshafen, and flies according to Hagen from December to March. The larva occurs singly on a climbing plant of the Convolvulus tribe, on which the ♀ lays the greenish eggs singly at the tip of the underside of the leaves. Both sexes lighter and larger than *turneri*, larger and somewhat darker than *georgina*. ♂: the greenish white, almost quadrate, costally somewhat incised spot before the apex of the cell of the forewing merged in the long stripe which runs out from the base of the cell. Cell of the hindwing with a thin brown-black fork, which in *turneri* fills up almost the entire cell, but in *georgina* is completely absent. All the circumcellular spots of both wings considerably larger than in *turneri* and *georgina*. The 3 strigae below the costal margin, which are placed close above the apex of the cell of the forewing, are nevertheless narrower and more isolated than in *georgina*. The submarginal area of the hindwing much more prominently dotted with white than in *georgina*, but only a little more distinctly than in *turneri*. *eugenia* is further intermediate between *tanais Fruhst.* from Mefor, from which it differs in the more broadly black submedian veins and the confluent cell-spots

metaxa. of the forewing, and *purpurata* from Waigeu. — **metaxa** *subsp. nov.* (77 a) affords one of the clearest examples of how species alter in the Tropics even at short distances. The greenish white areas of both wings are widened, the longitudinal streak at the submedian of the forewing and the fork-marking of the hindwing are either entirely absent or only vestigial. Properly speaking only the submarginal dots of the hindwing remain unchanged, being quite as complete, especially in the ♀, as in *eugenia*-♀ (78 a). One may describe *eugenia* as having the ♀ predominantly black-brown with whitish patches, whilst *metaxa* is a form with greenish white ground-colour and black margins to the wings. *eugenia* approaches *sobrinoides Btlr.* from the Bismarck Archipelago, whilst *metaxa* forms a transition to *georgina* from British New Guinea. *metaxa* is common at Stefansort and Finschhafen, principally in the rainy season, from September onwards.

georgina. Valve of *metaxa* and *eugenia* not distinguishable with a low-power lens from that of *juventa*. — **georgina** *Fruhst.* approaches *metaxa*, from which it differs in the shorter, more rounded subapical strigae and the rounder, smaller apical spot in the cell of the forewing, which is not confluent with the basal streak. Also the greenish white areas at both sides of the submedian are shorter, the submarginal dots of the hindwing are absent or reduced, in general also the black-brown marginal area of both wings more extended. Collingwood Bay, Milne Bay and Papua Gulf in British New Guinea. The occurrence of three separate Danaid-forms confirms the fact which has been long known of birds, but with regard to Lepidoptera was first shown by me in 1905 (W. Ent. Zeit. p. 57), that the mainland of New Guinea produces well differentiated local races of a collective species. The range of these forms is to some extent accidentally identical with the present political divisions of New Guinea, so that the Dutch and the German as well as the British district each has its own endemic forms. The varieties inhabiting Dutch and German New Guinea, however, are often not so sharply differentiated as those of the German and British territories. This fact is easily explained by the common coast-line of the two first-named and the absence of any separating mountains, whilst between German and the southerly British New Guinea the Bismarck and Finisterre Mountains and the Owen Stanley Range form a lofty barrier, impassable to many species.

Along the coast the deep indentations of Huon Gulf, Collingwood Bay and Milne Bay appear to serve as barriers. — **purpurata** *Btlr.* is the local race from Waigeu, and is the furthest removed from typical *juventa* and *meganira*. It surpasses even *metaxa* in the deep black margining of the wings and the large vitreous areas on both wings, and shows a strikingly broad black marginal area and only a thin cell-streak on the forewing. Median and basal areas of the hindwing almost pure white, particularly beneath without greenish tinge. Cell of the hindwing without any trace of a fork-marking. Submarginal patches very indistinct. *purpurata* might be claimed as a distinct species if it were not connected with the races of the main island by intergrades from the islands in Geelvink Bay. — **tanais** *Fruhst.*, from Mefor, very nearly approaches it and is only distinguished as follows: the greenish white areas on the forewing are darker, somewhat smaller; the spot at the submedian is divided by a broad black line; the submarginal dots reach to the lower median and are stronger; the spot in the cell is smaller, as are also all the transcellular patches. The lowest patch, however, between the lower medians, is intermediate in size between those of *purpurata* and *georgina*. The hindwing bears two fairly distinct rows of submarginal dots, as in *georgina*, whilst in *purpurata*-♂ only one row is visible. Under surface: all the discal spots smaller, darker and scaled with blackish brown. Submarginal dots much more distinct, larger and the rows more complete. — With **sobrinoides** *Btlr.* begin the most easterly races, which approximate closely to *eugenia* and even *meganira* and show either no cell-streak at all on the forewing or only an obsolete one and the cell of the hindwing much darkened. *sobrinoides* differs from *eugenia* in the more yellowish white areas on both wings, without a trace of greenish. Common on New Pomerania and New Lauenburg. — **ribbei** *Fruhst.* inhabits New Mecklenburg. ♂♀: considerably smaller than *sobrinoides*, the white markings reduced and the black-brown ground-colour consequently more extended. The submarginal rows of dots on both wings more obsolete, the cell of the forewing without the least trace of a white stripe and the cell of the hindwing begins to be much darkened in the upper part, as brown scales from the costal margin extend to the lower branch of the cell-fork. On the forewing the white spots at both sides of the submedian and also the patches placed beyond them are much narrowed, proximally pointed. On the under surface the wings are even more darkened than above, particularly the cell of the forewing. — **mangalia** *Fruhst.* In the *Radena* from the Shortlands Islands the white cell-streak of the forewing is connected with the white cell-spot and is not divided as in *tanais* from Mefor. Moreover, in the Shortlands ♂ the submarginal streaks are narrower and more curved and are divided by four of the much more broadly black veins. The anal fold is quite plain yellowish and not striped with black as in *purpurata*. In addition to the very noticeable absence of the black stripe in the anal fold of the hindwing *mangalia* further differs from *purpurata* in the complete submarginal row of white dots and in having the hyaline spots reduced as in *tanais*. From *tanais*, to which it is very similar, *mangalia* may easily be distinguished by having the patches on the hindwing further removed from the cell, and also narrower and more rounded. Shortlands Islands, Solomon Archipelago. — **zanira** *Fruhst.*, from Bougainville, scarcely resembles *purpurata* and *mangalia*, but leans more towards *sobrinoides Btlr.* from New Ireland. From this *zanira* is easily distinguished by larger size and the much darkened markings. All the white spots are reduced with the exception of the submarginal dots of the hindwing, which are more distinctly developed. *zanira* forms a connecting link between *turneri* and *sobrinoides*, being somewhat lighter than *turneri*, but darker than *sobrinoides*. The streaks at the submedian of the forewing are likewise intermediate between the two races, as also the circumcellular spots of the hindwing. The under surface of the wings is very characteristic, bearing extremely prominent, pure white spots and dots, while in both the allied races these are more grey and green-white and quite distinctive. Bougainville, Solomons. Very common. — At the first glance it may appear rash to unite under one species the almost scaleless and diaphanous Javan *juventa* with the almost entirely black *turneri* or *sobrina*, but even under the microscope it was not possible to establish the very slightest difference in the sexual organs between the widely separated geographical races. Hence it may be unhesitatingly concluded that *juventa* must be regarded as the lightest and most easterly form, the Celebes and Molucca races as connecting links and those from Papua as the most extreme melanotic offshoots of a single species. The eastern representatives of *juventa* are slightly scaled and hence very transparent, whilst the Papuan races with almost the entire surface of the wings covered with black scales are scarcely transparent at all.

purpurata. *tanais.* *sobrinoides.* *ribbei.* *mangalia.* *zanira.*

2. Genus: **Ideopsis** *Horsf. & Moore.*

This genus was formerly regarded as an intermediate form between *Danaida* and *Hestia*, as with its vitreous wings and general scheme of markings it presents to some extent the aspect of a miniature *Hestia*.

But the clubbed antennae and particularly the genitalia distinguish it from *Hestia*, as also its generally very striking sexual dimorphism. In neuration the species approximate to the *Radena*-group of *Danaida*, having like these the first subcostal vein of the joining with the costal — and also the arrangement of the modified scales along the submedian of the hindwing is the same. The androconia are arranged in undulate lines and are most widened in *vitrea* — whilst in *iza* they stand out most strikingly as deep

black bands from the pure white ground. The upper discocellular of the hindwing is longer than the others, in which *Ideopsis* differs from *Radena*. But the genitalia have no connection at all with *Hestia* and approximate to *Radena* in the similar non-dentate valve, which shows only a ventral point. Uncus somewhat shorter than in *Radena* with two short bristle-bearing appendages resembling a roller or willow-catkins.

The early stages are unfortunately not yet known, for what HORSFIELD and MOORE figured as such in 1857 belong without doubt to *Hestia malabarica* or *agamarschana*; but it is tolerably certain that larva and pupa resemble those of *Radena* more than of *Hestia*.

Precostal of the hindwing originating at the origin of the subcostal vein as in *Danaida* and the claws simple, without paronychia, which indicates a further difference from *Hestia*.

The antennae of the ♂♂ are more abruptly clubbed than those of the ♀♀, whose antennae approximate more to the Danaid form, in the ♂ 8—9 segments, in the ♀ 10—11, are united to form the club.

The species of *Ideopsis* mostly occur in company with Hestias and like these are fond of flying up and down along streams in the woods, in shady places but when the sun is bright, especially in the morning; their flight is Danaid-like and lacks the slow, majestic sailing motion of *Hestia*.

Ideopsis is a purely Malayan genus, inhabiting the whole of Macromalayana, the Philippines, Celebes and all the larger Moluccan islands, but wanting in Micromalayana and also on the Aru and Key Groups, and its most eastern offshoot reaches Dutch New Guinea.

Structurally the species are broken up into two groups: a) With elongate clubs to the antennae, which are well rounded (transverse section). 2nd subcostal of the forewing arising at the apex of the cell, so that the upper discocellular is wanting. *Ideopsis Moore*. b) With oval clubs to the antennae, which are compressed. 2nd subcostal arising before the apex of the cell, so that there is a distinct upper discocellular. *Aianthis Fruhst.*

Group Ideopsis *Moore* (= Gamana *Moore*).

All the species with *Hestia*-like grey, semitransparent wings.

gaura. **I. gaura** *Horsf.* inhabits eastern and western Java and occurs locally from the coast-forests up to about 800 m. throughout the whole year. ♂♀ similar to *costalis* (76 a), but with more extended black markings, in which are placed large, white, roundish submarginal patches. On the other hand the black spot at the apex of the cell of the hindwing is but little developed.

I. daos is very susceptible to climatic influences and is broken up into a series of island races, both Sumatra and Borneo even having two separate local races. The species reaches the maximum of *perakana.* its development on the Malay Peninsula, where occurs **perakana** *Fruhst.* (76 a), distinguished by its size, the milk-white ground-colour especially in the ♀ and the large black patches at the apex of the cell of both wings. The submarginal row of spots on the forewing does not increase in size so regularly and gradually as in *gaura* and the other forms of *daos*, on the contrary the three upper subapical dots are very small, but the following three very large, without any intergradation. On Penang MARTIN found the butterfly in company with *Hestia linteata Btlr.* When at rest large specimens of *perakana* were not distinguishable from small *Hestia*, but they were known at once by their flight, which is more rapid in *natunensis.* *Ideopsis* than in the sluggish *Hestia*. — **natunensis** *subsp. nov.* closely approaches *perakana*, has the same expanse and the patches at the discocellular of the same size, but the black submarginal spots of the forewing are essentially smaller and more elongated, and the median veins more thickly bordered with *daos.* black. Natuna Islands, not rare. — **daos** *Bdv.* is the name-type, probably from South Borneo. Ground-colour, particularly that of the ♀♀, smoke-brown, which in the ♂♂ is also noticeable beneath. ♂♂ with *infumata.* specially dark upper surface MARTIN has called f. **infumata.** Very common at Banjermasin in South-*ardana.* East Borneo and at the Kapuas River in South-West Borneo. — **ardana** *subsp. nov.* is probably the mountain race of Northern Borneo, taken by WATERSTRADT in large numbers at the Kinabalu. Both sexes appreciably smaller, the black patches somewhat reduced, the ground-colour more uniform, dark, vitreous, without brown or whitish tinge and even the white marginal spots of both wings less developed. — *palawana.* **palawana** *subsp. nov.* is the form from Palawan, which is still more dwarfed than *ardana*, and in which the black submarginal patches of the hindwing are placed very near to the marginal spots and like all *lingana.* the other spots are smaller than in *ardana*. — **lingana** *subsp. nov.* forms the transition from *perakana* to the race from north-eastern Sumatra and is exactly intermediate in size between the two. It has in common with *perakana* the distinct cell-spots and the very broadly black costal margin of the forewing, but the ♀ is coloured like that of *sonia*. Islands of the Lingga Archipelago to the south of Singapore. — *sonia.* **sonia** *Fruhst.* is a small form approaching *costalis*, but with lighter ground-colour in the ♂, the ♀ with the submarginal patches of the hindwing twice as large and the median veins of the forewing very broadly *eudora.* black. Common in the Sultanat Deli, North Sumatra. — Finally, **eudora** *Gray* is the West Sumatran mountain race, with dark vitreous areas on both wings as in *ardana* from North Borneo. Neighbourhood of

Padang Pandjang, West Sumatra. — **costalis** *Moore* (76 a) is one of the commonest butterflies of the island of Nias. — A closely allied form occurs on the neighbouring Batu Islands, which has been described from Pulo Tello as **batuna** *Fruhst.*, with still more reduced black submarginal patches on the hindwing. The costal margin of the forewing unicolorous black, suppressing the wedge-shaped white spots which adorn the other subspecies of *duos*. — **nigrocostalis** *Hag.*, from Mentawej, has the basal half of the costal margin and the upper part of the cell on the forewing more strongly blackened than *costalis*. Only ♀♀ known. *costalis.* *batuna.* *nigro-costalis.*

Group Aianthis *Fruhst.*

I. anapis, the only species known from the Philippines, approximates closely in the colouring to the Philippine *Hestia*. becomes darker as one proceeds southwards, is broken up into a series of island races, and shows at the base of both wings the yellowish tinge so characteristic of *Hestia leuconoë*, which likewise increases from north to south. — **anapis** *Fldr.*, from Manila and the adjacent Sierra de Mariveles, is a somewhat darker race than the pale **bracara** *subsp. nov.*, from North-East Luzon, figured by Semper, in which the upperside of the hindwing shows only an obsolescent delicate yellow tinge and the subapical spots remain pure white, not enclosing any black. — **anapina** *Semp.* is a highly specialized form from Mindoro, of which I have before me a pair collected by Dr. Platen. The black transverse band of the forewing in the ♂ is appreciably broader and the submarginal patches on the hindwing are enlarged. The latter shows only at the basal part of the cell a yellowish tinge, which in **glaphyra** *Moore*, from Mindanao, extends over the whole cell. The costal border also covers the anterior half of the cell of the forewing, but the spot at the apex of the cell is not united with the distal border as in *anapina*. Cell of the forewing in both sexes with black apex, which is likewise wanting in *anapina*. — **messala** *subsp. nov.* is the race from East Mindanao, figured by Semper, which is known from 8—900 m. above sea-level; it is an albinotic extreme of *glaphyra* and is characterized especially by the absence of the black patch at the apex of the cell of the hindwing in the ♀♀ and the very narrow black bands in both sexes. The subapical area of the forewing does not show the extended black spots which Moore mentions in *glaphyra* and which are distinct in my examples from West Mindanao. *anapis.* *bracara.* *anapina.* *glaphyra.* *messala.*

I. vitrea is unquestionably the most beautiful of all the species of *Ideopsis* and not only occurs on all parts of Celebes but also extends to the Moluccas and western Dutch New Guinea. But singularly it is not found on Bangkai and the Sula Islands, where it is replaced by a much smaller, entirely different species. — **vitrea** *Blanch.*, the name-type, inhabits North Celebes, where it is not rare both in the Minahassa and at Toli-Toli and forms one of the ornaments of the woods with its slow flight and the magnificent yellow border of its hindwing as well as by its abundance. The ♀ has more rounded wings and on the forewing also two complete rows of yellow patches before the distal margin. The black band of the hindwing is sometimes only indicated and also in the ♂♂ much narrower than in the figure, which is drawn from a ♂ from South Celebes, a form which is here introduced as **arachosia** *subsp. nov.* The median band of the hindwing in the ♀♀ is broad from the apex to the lower median vein, whilst in *vitrea* between the middle and lower median veins it is usually more streak-like or is altogether so little developed that it may be regarded more as a widening of the blackish dusting on the vein. Also beneath the distal margin of *arachosia* is much broader, the yellow ornamental band correspondingly narrower and the yellowish submarginal dots more indistinct. The species is to be met with all the year round at the waterfall of Maros. — **chloris** *Fldr.* (76 b), described from Batjan and Halmaheira, shows all the white patches of *vitrea* yellow-coloured. The submarginal half-band of the hindwing begins broad at the apex and ends at the upper median. The subterminal patches on the underside of both wings and sometimes even the submarginal spots of the forewing in the ♀♀ are white and contrast vividly with the sometimes lighter, sometimes darker yellow intramedian areas of the proximal parts of the wings. Cell of the hindwing sometimes with brown fork-mark. — **neleus** *Fruhst.* differs from *chloris*-♀ in the brown instead of black ground-colour of both wings. The hyaline patches are dull and darker yellow. All the submarginal dots smaller and yellowish, instead of pure white. The first two transcellular yellow spots broader. The brown-black distal border encroaches on the yellow discal band with narrower but more pointed and longer wedge-spots. The blackish apical spot of the hindwing is broader than in *chloris*, the first three submarginal spots are smaller and strongly incised. The forewing more rounded, the whole build smaller than in *chloris*. *neleus* must be very local on Buru, as only ♀♀ are yet known and Doherty, who collected for a long time on the island, did not meet with it at all. — **obiana** *Fruhst.* (76 c), from Obi, again approximates decidedly more to *vitrea*, as the yellow-colour of both wings is lighter and in the ♀ the middle of the wing is white, though not transparent. The yellow areas in both sexes are moreover much more extended and the posterior half of the cell on the forewing not black, but likewise a beautiful light yellow. The yellow or whitish submarginal wedge-spots on the underside of the forewing in the ♀♀ are only separated from the median area by small brown lunules, cell of the hindwing without any trace of a fork-mark. Not rare. — **arfakensis** *Fruhst.* has the cell of the forewing completely transparent and the median area vitreous, while the yellowish submarginal patches are especially strong. Only the submedian part of *vitrea.* *arachosia.* *chloris.* *neleus.* *obiana.* *arfakensis.*

the forewing tinged with yellowish, hindwing similar to that of *chloris*. Hence the forewing of *arfakensis* recalls *vitrea*, whilst the hindwing has distinctly preserved the *chloris*-character. Appears to be very rare, as I have only received one pair.

ribbei. **I. ribbei,** a very rare species, of which there are only two island races to record. — **ribbei** *Röb.*, from Bangkai, of which apparently only ♂♂ have been taken, as the ♀ is still undescribed. ♂♂ with broad black distal border and narrow grey-white longitudinal stripe in the cell of the forewing, otherwise like a *vitrea* in miniature, except that the submarginal band of the hindwing is also grey-white instead of *iza.* yellow. — **iza** *Fruhst.* (76 c) has the cell-stripe of the forewing almost twice as broad and the submarginal patches much larger. On the hindwing the black teeth of the distal border project further into the vitreous area than in *ribbei.* ♀ with three large subapical stripes on the forewing. Sula Mangoli. Flies October—November.

klassika. **I. klassika** *Mart.*, a sharply differentiated species, has the ground-colour entirely black-brown with straw-yellow submarginal, subapical and median patches and is said to recall *D. menadensis Moore* in the arrangement of the markings and to form a sort of transition from *Ideopsis* to *Danais*. Only 3 ♀♀ are yet known. Ceram.

inuncta. **I. inuncta** *Btlr.* (76 b), with the black markings even more simplified than in *iza*, especially the distal border of the hindwing only slightly dentate proximally, the submarginal spots of the forewing only separated by fine black margins from the median area, which is transparent in the ♂♂, milky white in the ♀♀, base of the forewing in both sexes tinged with brilliant yellow. Marginal area of the wings beneath black-brown with white submarginal dots and large quadrate white submarginal spots on the forewing. Abdomen above brown, beneath grey-white. Waigeu, ♂ evidently very rare, as only one ♂ is *hewitsoni.* taken to about 20 ♀♀. — **hewitsoni** *Kirsch* is the only branch race yet known, from the island of Mysore in the north of Geelvink Bay in Dutch New Guinea. The yellowish tinge of the forewing is entirely absent, as also the brown double line in the cell of the hindwing, and it differs further from *inuncta* in the broadly brown veins of both wings.

3. Genus: **Hestia** *Hbn.*

All the species which belong here are distinguished by their size and have a heavy, awkward flight, the weak muscles being evidently unable to control the enormous wings. Even a moderate breeze drives them helplessly hither and thither like pieces of light paper and probably on this account they never leave the shelter of the woods. The species of *Hestia* are among the largest butterflies, and they even attract the attention of the natives, who in India call them „spectres" or „ghosts", the Malays on Celebes give them the expressive name „surat", i. e. letter, and the Javanese that of „kupo kertas", i. e. paper-butterfly. The butterflies are mostly gregarious, are fond of following the course of small streams, above which they float up and down, also frequently gambol round high flowering forest-trees and love to settle in the late afternoon on projecting twigs, mostly in pairs, so that one might think they were beginning family life. The imagines are large, semitransparent butterflies with long, very thin antennae, scarcely thickened at the tip, without clubs or knobs. Claws, unlike *Ideopsis*, with appendages. The precostal of the hindwing arising distally to the subcostal, being bipartite and directed proximad. Forewing with five subcostals, of which two arise before the end of the cell, the first being united with the costal as in *Ideopsis*. Hindwing without patches of androconia or other scent-organs. ♂♂, however, with two or four scent-pencils at the anal extremity. The *Hestia* differ from all other Danaids in the broad and always sharply armed valve, which is coarsely dentate or provided with widely projecting points, and form a group by themselves. The uncus is aborted. Larva of only two species yet known, approaching those of the Euploeid-group *Trepsichrois*, long, black, ringed, with lateral variegated patches above the prolegs and provided with four pairs of fleshy black tentacles. Pupa more slender than the bell-shaped pupa of the Danaids, with projecting points at the head, yellowish, black-dotted, without golden ornamentation.

The genus *Hestia*, like *Ideopsis*, may be separated into two groups:

a) The second subcostal vein arises near the apex of the cell. Lower discocellulai very short. Abdomen with four anal pencils of equal length. . . . . Hestia *Hbn.*

b) The second subcostal vein arises at a great distance before the apex of the cell. Lower discocellular of the hindwing long. Abdomen with four anal pencils, two of which are much abbreviated . . . . . Nectaria *Dalm.*

Group Hestia.

H. jasonia is the species of the genus which has extended furthest towards the west, with offshoots to Ceylon and the Andamans and northwards distributed to Tenasserim and Assam, but only occurring

at the southern point of the Indian peninsula. — **kanarensis** *Moore*, described from North Kanara and South Konkan, is a small race with blue-white, semitransparent wings, with two black isolated patches in the cell of the forewing, veins of both wings at the distal part with cuff-shaped figures, which are proximally widened as in *fumata* (74 b). Upon these follow at a less distance than in *fumata* a row of irregularly shaped submarginal patches, and there is an oblong subbasal spot at the submedian vein and a rounded patch between the median veins below the cell-wall. Markings of the cell otherwise as in *fumata*, but all the black spots smaller. Flies from January to the end of March at about 500—600 m. — **malabarica** *Moore* is a race which so closely approaches *lynceus fumata* in the strongly widened black spots and in its size that by earlier authors it was cited in the local lists of Indian butterflies as *lynceus*. It is, however, a subspecies of *jasonia*, although again *jasonia* must be regarded as only the western representative of *lynceus* from Anterior India and Ceylon. The butterflies are common, though they are said to be difficult to catch, as they fly high. They have, however, the habit of sailing slowly down from the tops of trees with the wings outspread, describing wide circles, sometimes approaching the surface of small mountain streams, where they hang for a time over their own reflection, and then return again to their tree-tops in as ghostly a manner as they appeared. According to Moore they do not seem to occur below 300 m., but ascend to 1200 m. The butterflies fly all the year round and are reported as occurring abundantly from February to April and again from August to November. Egg white, oval, with longitudinal rows of hexagonal grooves, fastened singly on leaves. Larva cylindrical with small head, black with legs of the same colour and four pairs of tentacles, broadly ringed with white with red lateral patches above and between the prolegs. Pupa yellowish, canoe-shaped, covered with black streaks and dots. Pupal stage 18 days. The larva when first hatched yellowish, but with black head and legs, eating holes in the middle of the leaf. Only when it becomes larger does it begin to attack the edge like other larvae and mostly remains on the underside of the leaf. The larva takes 20—25 days to feed up. As food-plant an Apocynaceae, Aganosoma cynosa, is known. Malabar. — **jasonia** *Westw.* occurs commonly on Ceylon, especially in the northern part of the island. In general somewhat darker than *malabarica*, more yellowish instead of white, with all the black markings enlarged. The black costal spot and the transverse band in the cell of the forewing always joined together. There are also ♀♀ with the under surface of both wings suffused with black-brown (**diabolica** *form. nov.*). Larva, which was first discovered in 1899, on a climbing plant allied to the genus Hoya, dark velvety black with broad pale yellow rings and ornamented with a lateral carmine-red spot on each segment from the sixth to the twelfth. Pupa unknown, but from the evident relationship to *malabarica* certainly very similar to that. Butterflies only a few feet above the ground, always in woods and by preference in the neighbourhood of water. In the late afternoon they are so tired or sluggish that one can go round among them, and even strike with the net, without the neighbouring butterflies being frightened away. They are said to ascend to 5000 ft. above sea-level. — **agamarschana** *Fldr.* inhabits Tenasserim, where it is said to be not rare in mangrove-swamps. It differs from *jasonia* in the much widened subapical cell-band and submedian band on the forewing, whilst the hindwing is scarcely distinguishable from that of *kanarensis*. In the Mergui Archipelago a larger, paler race is said to occur. — **arrakana** *subsp. nov.* is a local race with yellowish instead of whitish wings and with the apical spots of the forewing less sharply expressed and more confluent. Akyab, Arrakan. — **margherita** *Fruhst.* differs in the still darker ground-colour with much broader black distal border to the hindwing above. Margherita, Upper Assam, discovered by W. Doherty. — **cadelli** *Wood-M.* reaches the maximum in the progressive development of the black markings, which on the forewing only leave a very narrow white subapical area and a median area about the width of the thumb. The hindwing is bordered by a compact black band and both the cell-spot and the submarginal patches are almost twice as large as in *kanarensis*. Hitherto only known from Port Blair, where it flies chiefly in April.

kanarensis. *malabarica.* *jasonia.* *diabolica.* *agamarschana.* *arrakana.* *margherita.* *cadelli.*

H. hadeni *Wood-M.* (75 b) is perhaps only a branch form of *jasonia*, but as it is treated by all authors as a species, I follow their example. The white subapical area of the forewing is entirely suppressed by the deep black margin, which is almost uniformly broad on both wings. The species is very rare and has only been found as yet near Bassein at the estuary of the Irawaddi.

hadeni.

H. lynceus, a purely Macromalayan species, of which hitherto five local forms have been described. The name-type **lynceus** *Drury* probably came from Sumatra and is based on a ♀ with white-grey ground-colour. All the races belonging to *lynceus* are distinguished by a dense black dusting on the upperside of both wings, which in the allied species *logani Moore* is only feebly present, and a broad stumpy valve with only two ventral points and appreciable dorsal notch. All the forms, and also those of *logani*, bear a black spot at the subcostal of the hindwing, which is very dissimilar in shape, and varies in that it is sometimes only punctiform, but is occasionally continued as a narrow band to the costa. The costal area of the hindwing in the *lynceus*-group always bears two further black spots, a central one, which is placed free, and a subbasal which touches the cell-margin. *lynceus* is not rare on Sumatra and in the Deli Sultanate quite as common as in western Sumatra. According to Martin it is not found in the plains but at the outer slopes of the mountains, where the rainfall is larger than in the alluvial land, and

lynceus.

from the west of Sumatra it has only been sent to me from Padang Pandjang from elevations of about
reinwardti. 600—800 m. — **reinwardti** *Moore* is even larger and the roundish black patches on both wings are of great size, about one third larger than in *lynceus* from Sumatra. Perak and other parts of the Malay
niasica. Peninsula. — **niasica** *Fruhst.* on the other hand is a smaller race with the ground-colour more yellowish white instead of blue-black, which is particularly noticeable beneath, the wings more rounded, the black
favorinus. spots less developed, especially those in the cell of both wings. Nias. common. — **favorinus** *subsp. nov.* is the form which is called *fumata* at 74 b, and differs from Sumatran examples in the narrower wings and in having the ground-colour slightly inclined to grey-brown. The black patches smaller and especially those in the cell of the forewing more rounded. North Borneo, Kina Balu district and occurring at the
fumata. west coast of Borneo southward to Pontianak. — **fumata** *Fruhst.*, described from Amuntai and Banjermasin in South-East Borneo, deserves its name on account of having the upperside of both wings entirely suffused with dark smoke-brown, the underside being predominantly tinged with yellowish white instead of blue-white, as in *favorinus*. The dorsal part of the abdomen is likewise brown, instead of deep black, as in *lynceus* and *favorinus*, the roundish patches of both wings above dull brown-black instead of deep
stolli. black, as in Sumatra and North Borneo examples. — **stolli** *Moore* is inferior in size to all previously mentioned forms of *lynceus* and is of a lighter, grey-white colour throughout, which is a matter of course in a Javan butterfly, as all the species of this island, compared with their representatives from other districts, are distinguished by albinotic colouring, probably on account of the long dry season to which they are subjected. The black spots are analogous to those of *favorinus*, but especially on the forewing characterized by a more pointed and wedge-shaped instead of rounded form. Cell-patch of the hindwing mostly very small. *stolli* is rare both in the east and west of Java, on the other hand it was easy to catch
thalassica. 40—50 examples of the allied species *logani* in one morning. — **thalassica** *subsp. nov.* inhabits the Natuna Islands; it even surpasses *stolli* in its light ground-colour, but approximates closely in the arrangement of the markings to *favorinus*, with which it has also the size and wing-contour in common.

H. logani only differs from *lynceus* in the lighter ground-colour and the reduced brown or blackish scaling on the upperside of the wings, also as a rule it is somewhat less spotted with black, the knob-like widening of the submarginal patches of the hindwing more delicate, removed further proximed, and the rounded dots at the submedian of the hindwing show a tendency to obsolescence, as well as the black bordering at the discocellular of the forewing. But these are trifling differences, and have led Nicéville among others to accept *lynceus* and *logani* as merely forms of one species, between which no distinguishing line can be drawn. But nevertheless the valve shows characters of such decisive significance that the specific rank of *logani* cannot be questioned. The valve of *logani* is scarcely half as broad as that of *lynceus*, dorsally with a concave excision for more than half of its extent, and with a projecting distal part which is sharply dentate, much more recalling that of *d'urvillei* from New Guinea than that of *lynceus*. *logani* is like *lynceus* a purely Macromalayan species, and there are the following races to record:
logani. **logani** *Moore*, from the Malay Peninsula, very large, grey-white, with stronger black patches than **druryi**
druryi. *Moore*, which inhabits the alluvial plains of Sumatra and particularly in the west of the island is apparently much rarer than *lynceus*, with which it flies at the same time. This is only an unimportant modification of the preceding, ♀ somewhat more yellowish than Perak ♀♀ and with the black markings very
donovani. slightly reduced. — **donovani** *Moore*, described from Singapore, is perhaps only a dry-season form and is
diana. based upon an example of small size. — **diana** *Fruhst.*, described from a ♀ from the Batu Islands, is still lighter and more transparent than *druryi*-♀ from Sumatra. The black spots more reduced on both wings, the underside darker, the upperside on the contrary lighter grey. The cell of the forewing is traversed by 3 black longitudinal lines, which are separated basally, not forked. All the 3 lines connected by a rounded transverse spot shortly before the apex of the cell. Cell of the hindwing with 2 longitudinal lines, of which the upper one is forked shortly before the end of the cell. The round spot in the cell and the 3 spots at the costal margin more reduced than in the allied races. It is interesting to observe that the Batu Islands produce the light *logani*, the neighbouring Nias on the contrary exclusively the dark
alcine. *lynceus*. — **alcine** *Fruhst.* (74 b), easily recognizable by the almost completely obsolescent black spots in the cell of the forewing and above the submedian of the hindwing, has beneath a dull yellowish silky gloss. Only known to me from Pontianak, where it occurs together with *favorinus*. In South-East Borneo
virgo. occur ♀♀ with *alcine*-pattern, but like *fumata* lightly suffused with smoke-brown. — **virgo** *Fruhst.* is a race from northern Borneo with the general colouring more black-grey and the cell-spots somewhat stronger,
alceste. but the knob-markings on the submarginal part of the hindwing reduced. — **alceste** *subsp. nov.*, an extremely elegant light race from the Natuna Islands with entirely vitreous wings, without a trace of a yellowish or brownish tinge as in the local forms of the main island. — It is most nearly approached by
mevaria. the somewhat larger **mevaria** *subsp. nov.*, which again shows very well-marked black spots on both wings, but less developed than those of *lynceus stolli*. *mevaria* on the other hand is much smaller than *druryi* from Sumatra and has not hitherto been noticed, since also the *lynceus* race from Java differs, as mentioned above, from all the other *lynceus* forms by the whitish ground-colour being predominant. Not rare on Java and apparently on the whole the commonest *Hestia* of the island. Flies all the year round, but

especially in February—March, and occurs from the woods at the sea-coast up to about 500—600 m. — Finally, **hypata** *subsp. nov.* is a race of unusually small size, with the forewing strikingly narrowed and the black spots on both wings even less developed than in *alceste*. Sulu Islands, to the north of Borneo. On Palawan and also on the Micromalayan chain of islands beginning with Bawean and Bali no *Hestia* occurs, but whilst the genus *Ideopsis* extends to Palawan, it reaches its extreme limit on Java. *hypata.*

Group Nectaria.

H. hypermnestra is proved to belong to *Nectaria* by the rounded instead of elongate bag-shaped forewing and by the second subcostal vein arising far before the apex of the cell, and is a decidedly Macromalayan species. With the exception of Borneo, where it not only occurs in 2 local races but is also subject to the same colour-modifications as *Hestia lynceus*, it is very constant and scarcely varies in size and in the scheme of markings. — **hera** *Fruhst.* (74 c) is the Sumatran local form, occurring very sparingly in Deli Sultanate, but apparently not very rare in western Sumatra in the neighbourhood of Padang Pandjang (the so-called Bovenlanden). *hera* approaches **linteata** *Btlr.*, from Perak and Penang, but is apparently larger on an average, with the black patches enlarged and broader black stripes round the cell and along the veins, especially in the ♀♀, in which the cell-spot of the forewing is almost twice as large as in *linteata*-♀♀. *linteata* has been recently discovered in South Tenasserim also. — **belia** *Westw.* is a very rare race from Java, where in my experience it apparently only occurs in the neighbourhood of Palabuan Bay in the west of the island. In the course of many years I have only been able to obtain one pair, distinguished from *hera* by the more strongly expressed black spots on both wings and the specially thick black stripes on the radials of the forewing, while the ♀ has the ground-colour yellowish instead of pure white. — **vollenhoveni** *Fruhst.*, with the somewhat uncertain locality „Java", is known from a figure of Snellen van Vollenhoven's, which is noticeable for the smaller submarginal patches of both wings, the larger cell-spots and the darkened distal parts of the forewing. — **hypermnestra** *Westw.*, the race from southern and south-eastern Borneo and the Natuna Islands, occurs in 2 principal forms, which might be taken for separate species, but are connected by transitions. **belina** *Fruhst.* is the commoner, with both wings pure white above and beneath and hence very similar to *hera*, but with much smaller black wedge-spots and submarginal patches. *hypermnestra*, which might be taken for a rainy-season form, but which apparently occurs at the same time as *belina*, is as darkly scaled with smoke-brown as *fumata*, only the basal part, the upper end of the cell and the marginal area of the forewing have retained the original vitreous colour, producing a sharp contrast. The darkening, however, does not extend to the under surface, which is only somewhat more yellowish than in *belina*. It appears that only the ♀♀ show a tendency to the *hypermnestra*-colouring, and this also applies to **arbela** *subsp. nov.*, the geographical form of northern Borneo, which may be at once recognized by having the black patches on both wings more than twice as broad. ♂ white as in *belina*-♂, but with appreciable blue-grey sheen, ♀ more uniform, i. e. also tinged with smoke-brown in the distal parts of the wings. Abdomen more extended black on the dorsum than in *belina*. Kina Balu, apparently very rare. *hera.* *linteata.* *belia.* *vollenhoveni.* *hypermnestra.* *belina.* *arbela.*

All the forms of *hypermnestra* differ from the *lynceus-logani* group in having two isolated black rounded patches in the costal area of the hindwing and in the absence of the black streak at the subcostal vein.

H. leuconoë must be regarded as the most variable and widely distributed species of the genus. It has in common with *hera* the absence of the black streak at the subcostal and the two isolated black patches in the costal area of the hindwing, but differs from it in the still more rounded wings and the confluent submarginal patches of the hindwing, in which the harpoon-pattern of the *lynceus-hera* group disappears. The Philippines must be considered as the centre of distribution of *leuconoë*, whence it has reached the Sangir and Talaut islands in the south of the archipelago, singularly without extending to Celebes. Northwards it has reached the central Loo Choo Islands and entered northern Borneo (Sandakan) by way of Palawan. Along the western satellite-islands of Borneo it has crossed over to the Malay Peninsula, being known from Billiton and Banka, and having recently been discovered also on Engano and the Batu Islands. — **riukiuensis** *Holl.*, a characteristic butterfly of the Loo Choo Islands, represented in every consignment received thence. It is a summer species, flying principally in the second half of July and the first half of August. At the end of March and the end of August only worn specimens are met with. It is very variable and bears of all known races the smallest and at the same time the most rounded submarginal spots on the hindwing. In the ♂♂ the patches between the radials of the hindwing are also isolated, but in the ♀♀ they are confluent. ♂♀ on the upperside of both wings tinged with intensive dark yellow, also the under surface, especially that of the hindwing, yellowish. — **nipponica** *Fruhst.* (74 a) is a seasonal form or island race of uncertain locality, in which the yellow tinge does not extend beyond the cell of the forewing and the hindwing remains pure white on both sides. — **clara** *Btlr.* inhabits For- *riukiuensis.* *nipponica.* *clara.*

mosa. For decades only the type in the British Museum was known, but my collector recently discovered it near the south-eastern point of the island, at Taihanroku, in large numbers. It flies there from March to August and is very variable in pattern and colouring. No two specimens are alike and I have before me ♂♀ with the upper surface almost entirely white together with others in which it is almost entirely yellow. Frequently also only the forewing is yellow, the hindwing white. The submarginal spots of the forewing form in the ♂♂ a continuous band, so that in general the increase of all the black markings may

missilia. be regarded as a characteristic of *clara* in distinction from the Loo Choo races. — **missilia** *subsp. nov.*, essentially larger than *nipponica* and with the same tendency to albinotic colouring, but with the submarginal bands of the forewing widened as in *clara* and characterized by a subanal transverse band on the hindwing, which extends from the upper median vein nearly to the submedian. Loo Choo Islands, more

solyma. exact locality unknown. — **solyma** *subsp. nov.*, from Camiguin de Luzon, is the hitherto unnoticed race figured by SEMPER as *clara*, which differs from all the other forms in three black intramedian bands about 1 cm. broad, placed obliquely above one another. Both wings are white, only the base slightly tinged with yellowish, and the submarginal markings of the hindwing, which is otherwise spotted as in

leuconoë. *nipponica*, very narrow. — **leuconoë** *Eschsch.*, the name-type from Luzon, is best compared with *esanga* (74 a), from which it differs on the forewing in the less developed black median bands, but more extended subapical spots and hence narrower white distal area. The hindwing shows insignificant black markings. The ♀ is only distinguished from the ♂ by more rounded wings and somewhat larger spot in the middle of the cell on the hindwing. According to SEMPER *leuconoë* flies all the year round, and examples exactly analogous to the name-type are only met with in southern and central Luzon, whilst at the east coast and in North-West Luzon appear already transitions to *solyma*, which in its turn leads over to *clara* from Formosa and *riukiuensis* from Loo Choo. — As a rule *leuconoë* from the southern Philippines are very

obscura. dark and on this account the race from South-East Mindanao has received the name **obscura** *Stgr.* In these the yellow shade which in *leuconoë* extends as far as in *clara Btlr.* is restricted to the basal region of the forewing, the white zigzag area of the marginal part of the forewing is suppressed by broadly diffuse black-brown subapical wedge-spots, the cell and all the veins are densely covered with black, the

samara. upper surface of the wings in the ♀♀ moreover powdered over with blackish. — **samara** *subsp. nov.* is a race in which the melanotic colouring has its maximum development, the yellow tinge completely dis-

moira. appears and the vitreous patches are still more reduced than in *obscura*. Island of Samar. — **moira** *subsp. nov.* on the other hand is a form which like those that SEMPER mentions from the island of Siargao again approaches *leuconoë* from Luzon, even recalling *solyma* in having the intramedian patches of the forewing in part isolated, in part only slightly connected by fine streaks. But *moira* differs both from *solyma* and *leuconoë* in the broader subterminal black bordering of both wings, and the ♀♀ decidedly approach *obscura* in the broad-margined veins and large, long, pointed wedge-spots of the hindwing. Island

princesa. of Bazilan to the south of Mindanao. — **princesa** *Stgr.* is a very large form with much abbreviated cell-

esanga. spot on the forewing and large, mostly isolated wedge-spots on the hindwing. Palawan. — **esanga** *Fruhst.* (74 a), with strikingly light ground-colour, is characterized by very large black median spots on the forewing and large round cell-patches on the hindwing. The yellow tinge is not very pronounced and the underside of the hindwing differs from all known forms in the large rounded spots in and below the cell. The white marginal area of the forewing extended as in *clara* by the reduction of the subapical row of

godmani. spots. Talaut Islands. — **godmani** *Oberth.*, from Sangir, is a very large, strikingly light race with small

nigriana. black spots. — **nigriana** *Sm.*, described from a pair from the Sulu Island Tanganac off the north coast of Borneo, differs from *leuconoë* in the more rounded wings; the distal third of the wing is darker, the marginal and submarginal whitish patches and irregular areas begin to disappear, hindwing intersected by darker brown veins. I suspect that examples from Sandakan (North Borneo) belong to *nigriana Smith*, they are distinguished principally by the narrowed, elongate-oval subapical streaks and almost entirely

chersonesia. black apex of the forewing and hence differ essentially from **chersonesia** *Fruhst.*, which is noticeable for an especially broad white submarginal area, equally developed on both wings. Also the black dentate bands are quite uniform, the subapical wedges not being placed so near to the distal margin as in *nigriana* and *leuconoë*. Malay Peninsula, Lingga Archipelago, Banka, probably also Billiton. — But whilst *chersonesia*

natunensis. shows a deep yellow tinge, in **natunensis** *Snell.* this disappears completely from the basal half of the forewing and the ground-colour is lighter than in *leuconoë*, according to its author. Natuna Islands, unknown

javana. to me in nature. — **javana** *Fruhst.* is about intermediate between *chersonesia* and *nigriana* and bears very large black subapical streaks on the forewing, which restrict the white submarginal area, though still leaving it more room than in *nigriana*. Hindwing with small black cell-spot and very distinct dentate band. The round spot between the middle and lower median of the forewing is absent (perhaps only an individual variation, but very noticeable as it is present in all my many *leuconoë*). North-West Java, type in coll. PAGENSTECHER, Wiesbaden. The form has only once been found, and one might be tempted to question the locality, if *javana* were not actually different from all the allied races. However, this *Hestia* may formerly have been more common on Java, but through the constant increase of population and consequent inevitable destruction of the forests for the purpose of cultivating rice, sugar-cane and

coffee, the butterflies have been deprived of their head-quarters in their favourite quiet woods. — **vedana** *Fruhst.* (74 a) inhabits the Batu Islands near Nias off the south-west coast of Sumatra. Scheme of markings somewhat as in *obseura* from Mindanao, but the ground-colour purer white, the subapical area somewhat more extended, upper surface of both wings without black-brown or velvety brown tinge. *vedana* is, nevertheless, one of the darkest forms of *leuconoë*. Of the original yellow colouring of the wings it only retains a slight tinge, inclining to greenish on the forewing and a delicate yellow shade on the basal half of the hindwing. Upper surface of the forewing: The upper part of the cell and the areas between the cell-wall and the submedian densely scaled with black. The black patch at the submedian the size of a pea, distally strongly pointed. The black transverse band in the cell unusually broad. The black distal border very broad, hence the arrows of the postmedian band confluent near the radials and at the anal angle. — **enganoensis** *Doh.* differs from *vedana* principally in the broader black markings, which is particularly noticeable on the underside of the hindwing. Engano. Flies in April. *vedana.* *enganoensis.*

H. electra, hitherto only known from Mindanao, where it occurs in two local races, differs from *leuconoë* chiefly in the apex of the forewing projecting as in *lynceus*. Both wings suffused with yellowish to the distal margin, the black cell-spot of the forewing does not extend to the costal border, nor posteriorly to the cell-wall. — **electra** *Semp.*, of which only 5 ♂♂ and 4 ♀♀ have yet been brought to Europe, comes from Taganito in East Mindanao, where it was observed from the end of May to the beginning of June. The ♀ bears more extended black spots on both wings than the ♂ and approximates more to the *leuconoë*-type. — **harmonia** *subsp. nov.* is a local race discovered by Dr. Platen in South-East Mindanao, with the upper surface of both wings essentially darkened and still broader black bands. *electra.* *harmonia.*

H. blanchardi inhabits Celebes and its satellite islands in a series of well separated races. On Muna and on the Tukan-Besi Islands off the south-east of Celebes much darkened forms occur, such as are also known from the Andamans, Pegu and New Guinea. All the forms of *blanchardi* have in common a broad valve, deeply excised distally and armed with 10—12 irregular serrate points. In the *idea*-group the proximal costal patch is much reduced, in the races from Celebes and the neighbourhood it is completely absent and the distal patch sometimes connects the costal and subcostal as a diffuse spot. The butterfly is everywhere common and in South Celebes they even frequented the villages, where they fluttered round the huts of the natives, hiding themselves in the bamboo thickets at night. Larva ringed with black and yellow, above the spiracles a broad, dull yellow lateral band, which is interrupted by the black transverse bands. Head, venter and legs black, as well as the filiform appendages on segments 2, 3, 5 and 11. — **marosiana** *Fruhst.* (75 c) is characterized by a brown-green tinge, which sometimes covers the surface of both wings and is most distinctly present in the ♀♀. The intraneural arrows very long and slender, only on the forewing sometimes widened. The black cell-spot of the forewing never reaches the costal margin. Both sexes show in side-light a bright violet reflection. South Celebes, especially the waterfall of Maros, where they often rested in copula on twigs in the woods and the pairs could be easily taken with the hands. Sometimes also they flutter round tall forest-trees, as I observed especially in the rainy season (January, February), when they are very rare, whilst from May to November they occur in great abundance. Valve with one very large dorsal tooth, whilst in **blanchardi** *March.* (= tondano *Vollenh.*) the distal part is uniformly dentate. — *blanchardi* is a lighter form, with the distal part of the cell and the median area of both wings pure vitreous white, the brown tinge confined to the basal part and the marginal area, the cell-spots much reduced. Under surface almost pure white, the intraneural streaks thin, without a trace of cuff-shaped widening, cell likewise only quite finely striped with brown. North Celebes, apparently rarer than *marosiana*, as it is never brought to Europe in any large numbers. Also at Toli-Toli I took but few examples in November—December. — **garunda** *subsp. nov.* I have hitherto thought that the East Celeban race should be united with *kuehni* from Bangkai. But as according to Kühn's figures (Iris 1887) the larvae differ considerably, I propose the name *garunda* for the form from the whole east of the island, which is much lighter especially in the ♀. The principal difference from *marosiana* and *tondana* consists in the deep black instead of brown intraneural stripes and the more sharply defined distal border of both wings on a lighter ground. On the under surface of the forewing the brown dentate band is likewise replaced by a black one, the awl-shaped markings of the hindwing are much more delicate. Collected in Central Celebes in July and August by Doherty, at Bonthain by Ribbe and at Tombugo by Kühn, everywhere common. Larva according to Kühn varying locally, but in general similar to that of *malabarica*. Judging from a drawing of Kühn's, the larva of the East Celebes race bears on all the segments lateral red patches of equal size above the stigmata, but that of the island of Bangkai only six large anterior and posterior patches and two small dot-like ones in the middle of the body. Moreover in the latter the black rings predominate, in *garunda* the white ones. Pupa metallic golden with dark brown margins to the wing-cases and the abdomen, as well as rows of black dots. In January the caterpillar is very common, especially on rainy days. — **djampeana** *Fruhst.* (75 c) closely approaches the preceding and differs in the still more pronounced black cell-spots, which in ♂♀ reach both the costal margin and the cell-wall, the intraneural stripes are broader, the cell-spot is nearly *marosiana.* *blanchardi.* *garunda.* *djampeana.*

always confluent with the black patch at the discocellular and the dentate band of the forewing is broader
phlegeton. beneath. Tanah-Djampea. — **phlegeton** *Fruhst.* (75 c) is distinguished by the broad, deep black distal border of both wings, the much darkened costal margin to the forewing and the extended irregular transverse band in the cell of the forewing. The black border is absent on the under surface, but it shows through from above, the stripes of the hindwing bear cuff-shaped markings, which are united into a
munaensis. continuous band on the forewing. Tukan-Besi Islands, to the south-east of Celebes. — **munaensis** *Fruhst.* approximates to the preceding, but the marginal border is less dark and not so sharply defined, on the other hand on the forewing appreciably broader and as on the hindwing more uniformly decreasing. Island of Muna near Buton. Only 1 ♂ known, which was captured by Dr. SARASIN on the 26th December 1895 and is in the Museum at Basle.

H. idea, one of the best known species and a characteristic butterfly of the Moluccas, occurs in great abundance particularly on Ceram. RIBBE collected there in a short time over 2000 examples. The species differs from *blanchardi* in an unimportant but constant character, namely the occurrence of large wedge-shaped submarginal patches on the forewing, frequently united into a band. Also as a rule the black dot in the middle of the costal area of the hindwing beneath is absent. Valve of more irregular outline distally, and deeply sinuate in the central part (*blanchardi* is here concave), the upper tooth more
novella. obtuse than in *blanchardi*. — Under the name **novella** *subsp. nov.* (75 b) are united three only slightly
idea. differentiated races from Banda, Goram and Ceram, which only differ from the long-known **idea** *Clerk.* (= agelia *Godt.*) in the narrower black transverse bands in the cell of the forewing and the somewhat smaller black markings. *idea* is one of the commonest butterflies on Amboina and Saparoea.

All the following races of the *aza-* and *d'urvillei*-group have in common a mostly narrow black distal border, which is composed of the confluent cuff-shaped figures of the intraneural streaks of the hindwing and encloses round white dots.

aza. **H. aza** *Bdv.*, from Buru, is very similar to **hertha** *Fruhst.* (74 b), from Sula-Besi, but
hertha. essentially larger, with stronger wedge-spots on both wings and the marginal bands nearly twice as broad. Moreover the spot in the cell of the forewing and the stripes in the cell of the hindwing
sula. are more distinct resp. broader. *aza* is rather rare on Buru. — **sula** *Nicév.* is somewhat larger than *hertha*, apical part of the wing with more isolated, i. e. narrower strigae, the marginal and submarginal markings narrower. The spots on the underside of the hindwing more strongly margined with black and the costal patch much larger than in *hertha*. Sula Mangoli. Valve essentially different from that of *idea*, narrower, more irregular, without central sinus and only armed with 2 very pointed teeth of
theia. equal length. — In **theia** *Fruhst.* (74 c) the wedge-spots of both wings are united with the black marginal band and shorter than in *aza*. *theia* is very common on the Northern Moluccas and passes under the name *agelia*, which, however, is a synonym of *idea*. Valve similar to that of *hertha*, but with only one very long
obiana. dorsal tooth and two short protuberances below it. — **obiana** *Fruhst.* (74 c) is an unimportant local form, only differing from *theia* in having the black colouring somewhat reduced. The transverse cell-spot of the
vosseleri. forewing in particular is narrowed. Obi, not rare. — **vosseleri** *Fruhst.* is smaller than *theia* and *obiana* and its forewing has the cell completely blackened and the black patches twice as broad. Under surface of both wings with very thick black veins, the white submarginal dots very small, partially absent. Locality unknown. Perhaps only a melanotic aberration of *theia*.

H. d'urvillei forms the natural continuation of the preceding species in the Papuan region, where, however, it reaches the limit of its range in the western part of Dutch New Guinea and the islands in Geelvink Bay. All the races belonging to it, of which, however, we only know a small part, have in common a broad black transverse band on the forewing and a strongly expressed black distal border on the hindwing, the extent and development of which vary according to the locality. The valve is characterized by a deep dorsal sinus, and a relatively narrow distal extremity, projecting more than in other species and provided with only 2 equally large teeth. A forest species like all the *Hestia*, and the
d'urvillei. Key race is said to fly about among the trees at a great height above the ground. — **d'urvillei** *Bdv.* (75 a). The name-type only occurs on Waigeu, where it is apparently rare, but as BOISDUVAL erroneously
nike. located it in New Guinea, the much darker **nike** *Fruhst.* (75 a) from Dutch New Guinea passes under this name in collections. *nike* differs from *d'urvillei* in the materially widened discal band, the darkened apex and the reduced white marginal dots on the forewing. Moreover, the intraneural streaks on the hindwing are more pronounced, united with the black distal border for a great distance. Dorey, Arfak Mountains
metris. and Kapaur. — **metris** *Fruhst.* (75 b), from Salewatti, is the darkest extreme of the species. The cell of the forewing is almost entirely blackened, the submarginal streaks are broadened and on the hindwing the black-brown border extends to the middle of the wing, moreover the cell-stripes of the hindwing are
hemera. stronger. — **hemera** *Fruhst.* from the island of Biak. The bands of the forewing are again narrower than in *nike* and *metris*, but still somewhat broader than in *d'urvillei*, and the marginal region of the hindwing is likewise essentially darker than in examples from the main island of New Guinea. Hence *hemera* forms

to **aruna** *Fruhst.* (75 a) from the Aru Islands, with extended, pure white distal area on the forewing and the black margin broken up into separate spots and with the cell-stripes wanting on the upperside of the hindwing, thus approaching **keyensis** *Fruhst.* from the Key Islands, which is characterized by very narrow black transverse bands, a black spot at the apex of the cell and short, awl-shaped interneural streaks. Moreover, the marginal band of the forewing is even more broken up than in *aruna*. Not rare on Great Key. *aruna.* *keyensis.*

4. Genus: **Euploea** *F.*

The genus *Euploea* with about 140 species constitutes the most extensive Danaid-group of the eastern tropics. They accord well together in their similar facies and the uniform style of colouring in spite of the difference in the shape of the wings and in the markings of the upperside. Ground-colour mostly brown to deep black, only in a few species of the Papuan region changing to violet or brown-white. Larva, as far as known, on Ficus and other plants with milky sap, either with 3 pairs of fleshy appendages (*Macroploea*) or 4 pairs of tentacles (*Crastia, Trepsichrois*). Pupa thick, bell-shaped, sometimes profusely ornamented with gold and silver.

One of the principal characters of the imagines consists in the concave inner margin of the forewing of the ♂♂ in most species, which is usually associated with shorter or longer glossy scent-stripes. The hindwing appears as if polished at the costal margin in the ♂♂ (scent-patch) and mostly possesses a cavity which is covered with mealy scales, often modified into a thick pile (*Trepsichrois*).

The androconia are mostly club-shaped or elongate, but consist in *Trepsichrois* of long, thin, wavy threads.

The anal pencils are different in every species and are projected by the butterflies by the pressure of an apparently light fluid which quickly fills in the stylus and presses out the hair-pencil. In some species this process is accomplished slowly; it is most rapid in *Trepsichrois*, which protrudes its apparatus in nervous haste and draws it in again, every time emitting afresh that acrid, peculiar smell, which also characterizes the abdomen of the female.

Some species do not emit a nauseous, but a mildly aromatic smell, such as the large, dull blue *camaralzemau*, which like all its nearest allies possesses at the same time the shortest pencils, which can only be projected with difficulty.

Satpinx bears two rosettes of hairs placed one above the other, and it needs a fairly strong pressure to project the inner (upper) tuft, which moves up and down as a small yellow ball in the stylus, but cannot be protruded by the specimen, so far as I was able to observe in Siam. The double tuft of hairs is most developed in *midamus*, which is even able to protrude the supposed weapon all at once. *Eupl. rhadamanthus* has the rosette light grey instead of yellow. Nicéville compares the anal pencils with holy water sprinkling-brushes; they are always stretched out perpendicularly to the plane of the body. Judging from my preparations of *Salpinx viola*, the anal pencils are placed laterally in a throat-shaped, oval opening with somewhat swollen rim and apparently exactly in the middle of the seventh and eighth tergite, in pairs. Their radiating hairs look to the naked eye like black dots, but under the microscope they are long, thick tufts of hair.

The first subcostal always arises before the end of the cell, nearly always free, only occasionally in a few *Calliploea* coincident with the costal. In all the groups subcostal 2 arises at the end of the cell, a character which in contrast to *Danaida* remains very constant. Upper discocellular always present as in *Hestia*, although in some species only very short. The tertiary sexual characters on the upperside of the wings are very variable and are scarcely sufficient to separate the species, but have nevertheless led earlier authors to erect over 25 genera.

But whilst among the Danaids some groups can be separated structurally, in the Euploeids in spite of the closest investigation not the least difference can be recognized, as they remain altogether constant in the neuration. At the same time some of the tertiary sexual characters are useful as distinguishing marks for the separation of series of forms, which, however, must always be regarded as only groups, without the slightest claim to subgeneric rank, such as must be accorded to some of the divisions of the Danaids.

The differences in the anal pencils might offer a better basis for subdivision, but at present we are only able to study them conveniently at the live specimens, and hence they are still practically useless.

In absolute contrast to the Danaids, and even to most other genera of butterflies (with the exception perhaps of the Brassolids), the clasping organs are of strikingly uniform structure. Form of the uncus in 16 species and forms examined not recognizable at all. Valve broad, distally shaped like a bird's head, the tip chitinized, with long shaggy hair all over, very slightly widened or narrowed according to the species, and only covered with teeth in a few species (*aegyptus*, *leucostictus*). Saccus likewise only varying slightly in shape. Penis unusually long, membranous.

Almost all the Euploeas have in common a nauseous smell, which in *mulciber* reaches the maximum of repulsiveness for the human sense of smell. Some species smell of mignonette, others again of honey and

vanilla. The smell is in general dependent on the food and we may assume that it probably protects the Euploeas from insectiverous attacks. It is true that Piepers observed on Java that birds caught and devoured living Euploeas in his garden in Batavia, which to some extent would prove the protection to be of less vital importance.

In general the Euploeids are fond of flowers and sometimes occur in great abundance. In Siam I observed in a half dried-up wood a positively ghostly swarm of the butterflies, hundreds of which were resting in the underwood in rows one above another, and when anyone passed through the wood they rose up in alarm, fluttering about in confusion like bats, but in a short time settling down again.

In Hong-Kong at the end of October I saw Euploeids clinging to the fiery red flowers of Hibiscus and occasionally I met with them in Siam in the dry season on rocks over which water trickled. In Tonkin *mulciber* frequented places on the road which were fouled with urine, also I repeatedly baited it with rags soaked in excrement, which often attracted dozens of individuals.

On the continent of India the first brood appears already at the end of February, when the Euploeids afford a charming spectacle in the forests, as they describe light curves with their mysteriously iridescent ultramarine pinions or move forwards in a straight line, only to dip down again afterwards as if to display anew their beautiful dress with complacent satisfaction.

They are all in the habit of flying from 9 o'clock till towards midday, then disappearing and only coming out again in large numbers when the sun is nearing the west.

Sexual dimorphism is more pronounced in the Euploeids than in the other Danaids, and has even in one case led to the erection of two genera for the two sexes of one species. Horodimorphism on the other hand only occurs in rare cases and even then not to any very marked extent. Euploeas are even more than *Danaida* attached to the plains. In the Malay Archipelago no species ascends above 2000 m; and even in the Himalayas only *core* and *mulciber* reach 7000 ft. All without exception love the moist, warm tropical climate, but they are never found at dry localities either hot or cold; they are fond of small, isolated woods in the midst of cultivated tracts, as well as the edges of woods. A large number prefer the wooded sea-shore and disappear when human activity disturbs the quiet of the woods, but others again fearlessly sail about in open places in the large towns of South Asia. Starting from two centres of distribution, continental India and New Guinea, the number of species rapidly decreases on the remote island groups. Northwards they are still numerous on Formosa, but on the Loo Choo Islands they become extremely rare.

In spite of the abundance of the individuals the complete life cycle is only known of extraordinarily few species. We may also still look for the discovery of many species and numerous island races, especially on the satellite islands of Sumatra, Celebes and New Guinea.

Group **Crastia** *Hbn.* (1816).

Larva with four pairs of fleshy appendages.

With recurrent vein in the cell of the forewing at the origin of the lower radial. Scent-patch of the hindwing absent. Anal pencil short, without double hair-pencil.

Subgroup a. Forewing without distinctly visible sexual stripes (*Nipara, Oranasma, Patosa, Sarobia, Vadebra, Lontara, Gamatoba, Menama, Tronga, Sabanosa, Adigama* [Moore 1883]).

E. climena is an inconspicuous species, distributed from the Nicobars and Engano to the Moluccas, at the same time one of the smallest known, but occurring in colour-variations according to the locality. A
simulatrix. pronounced inhabitant of the coast-lowlands and of remote islands. — **simulatrix** *Wood-Mas.* Above dark brown, the margins broadly lighter, ♀ throughout paler than the ♂, both wings in the ♂ unspotted above, only the ♀ bears a small violet-whitish costal patch. Under surface of the forewing as in all the other forms with a violet-white dot before the apex of the cell, three blue transcellular spots and occasionally some subapical patches. Hindwing likewise with a punctiform spot, and three to four beyond the discocellular. Nicobars.
enganensis. Very rare, unknown to me in nature. — **enganensis** *Doh.* (81 e). Above fine deep velvety black with a pure white dot before the end of the cell in the ♂♂ and three in the ♀♀. Hindwing, particularly that of the ♀♀, with distinct submarginal spots and a row of subterminal dots on the underside. The commonest *Euploea*
sepulchralis. of Engano, I have received over 100 examples taken in April, of which, however, very few are ♀♀. — **sepulchralis** *Btlr.* is a somewhat smaller and paler race, which occurs very commonly in the neighbourhood of Batavia. Hindwing of the ♀ with appreciably lighter, brownish white patch, which is somewhat more extended beneath.
terissa. West Java, Island of Bawean. — **terissa** *subsp. nov.* is the local form of Eastern Java, where it ascends to about 500—600 m on the spurs of the Tengger Mountains. Above it always shows a distinct white area on the hindwing, which beneath reaches to the apex of the cell, in extreme examples even occurring as a pure
elwesiana. white marginal area, so that there is a certain similarity on the hindwing to *E. euripon* (86 e). — **elwesiana** *Nicév.* is a smaller race, originally described from Bali, where, as well as on Lombok and Sumbawa, it is nowhere rare up to about 700 m. Hindwing with somewhat less white than *terissa*, under surface with almost
macleari. obsolete dots beyond the cell. — **macleari** *Btlr.* likewise resembles *terissa*, but is even smaller than *elwesiana*.

Only a few examples known. Christmas Island, to the south of Java. — **neptis** *Röb.*, from Flores, shows a distinct light patch, approaching *bandana*, on the forewing, on which, especially beneath, a light brown submarginal area is perceptible, the first traces of which are visible in *elwesiana* from Lombok. Hitherto only a few ♂♂ known. — **climena** *Cr.*, the name-type from Amboina, varies much in size, the darkest examples, probably belonging to the rainy-season form, have the forewing 46 mm in length, whilst ♂♂ and ♀♀ of **zinkeni** *Fldr.*, collected in August, only measure 36 mm and bear on the hindwing a whitish submarginal band, visible also above, which, however, is likewise always slightly indicated beneath in *climena*. Both forms bear very large white submarginal dots on the hindwing. — **melina** *Godt.* is a form without subapical dots on the hindwing beneath; likewise described from Amboina. Amboina, Saparoea, Ceram, very common. — **dohertyi** *Holl.* is a smaller race, as a rule without perceptible whitish or yellowish submarginal area on the hindwing beneath. Not rare on Buru. — **bandana** *Fruhst.* (82 d) forms a kind of transition to *eurypon* (86e), only the submarginal bands on both wings above are not white, but light brown, but beneath become distinctly white. Banda, not rare. — **sobrina** *Röb.* has the colouring of the under surface in common with *bandana*, but differs above in the darkened forewing, which shows a retrogression to *climena*, whilst the white marginal area of the hindwing indicates its relationship with *eurypon*. Goram. — **valeriana** *Fruhst.*, from the small island of Roma between Wetter and Dammer, to the north-east of Timor, shows a sharply defined quadrate white spot on the distally light, basally dark brown forewing and a whitish submarginal band on the hindwing above, distally changing gradually into brown. On the under surface the white patches are reproduced. — Finally, **eurypon** *Hew.* (86 e) constitutes the albinotic extreme of the entire series of forms, with broad, pure white marginal area on the hindwing, the brown ground-colour completely suppressed distally. On the under surface the white area extends to the apex of the cell. Common on all the Key Islands in October and November, but occurring in single specimens all the year round. — **vicina** *Fldr.* is an allied race of somewhat smaller size and with the white bands less developed. Aru Islands, unknown to me in nature. — **doretta** *Pagenst.* I think from examples in my collection should be referred to *climena*, from which it only differs in the more rounded wings, the rather dark and more unicolorous hindwing and above all in the smaller blue-white discal dots on the under surface. Bismarck Archipelago, New Lauenburg. — **mangoensis** *Btlr.* is a further, rare race of somewhat smaller size. Micronesia. — **misenus** *Misk.* Upper surface brown-black, hindwing with lighter brown anal angle and a submarginal row of only faintly indicated whitish dots. Under surface somewhat less dotted in *climena*. Described from Cape York, wanting in my collection.

neptis. *climena.* *zinkeni.* *melina.* *dohertyi.* *bandana.* *sobrina.* *valeriana.* *eurypon.* *vicina.* *doretta.* *mangoensis.* *misenus.*

E. lugens *Btlr.*, distinguished by the narrow, oval hindwing, appears to replace *climena* on New Guinea. — **smithi** *Moore* is an allied form, only known to me from the description; somewhat larger than *lugens*, forewing with white submarginal spots, of which the two lowest are equal in size, and a submarginal row of small white dots. Under surface as above, forewing with a small blue-white cell-spot and five insignificant discal patches, an arrangement which is repeated on the underside of the hindwing. New Guinea, without exact locality.

lugens. *smithi.*

E. palmedo *Doh.*, which its author compares with *lewa Doh.* (85 a), is an ally of *climena* and *compta* and similar to *adorabilis Fruhst.* (86e). Forewing dark brown, distally paler, with a quadrate white subapical spot, which is divided by three thin dark veins. Hindwing above the subcostal vein nearly white, the median part brown, the distal and subanal region appreciably lighter. Forewing with a blue-white cell-spot and two discal patches, also traces of stripes between the lower medians. Hindwing likewise with cell-dot and six very small circumcellular dots, as well as a row of 6—7 larger spots in the yellowish discal area. Only one or two small submarginal dots. Rare in the interior of Sumba. — According to Doherty a similar species occurs on Sumbawa, with the margins broadly whitish and without the white subapical spot on the forewing (possibly *climena elwesiana Nicév.* is meant). — **adorabilis** *Fruhst.* (86e), which I formerly united with *compta Röb.*, I now unhesitatingly refer here as a further Micromalayan race. Upperside as in the figure, with vivid dark blue-violet reflection. Underside differing from that of similar races of *climena* in a row of sharply expressed subterminal dots and a complete row of white submarginal dots, which latter are placed in quadrate white areas, proximally bordered with brown-violet. Wetter, very rare, only 2 ♀♀ in coll. Fruhstorfer.

palmedo. *adorabilis.*

E. compta, an extremely handsome species, inhabits all those eastern islands of the Timor and Timor-Laut Groups on which *climena* does not occur, and may possibly be specifically identical with the *climena*-series. The most essential difference from *climena* consists in three strongly expressed white patches on the forewing and a postdiscal band of six very large white spots on the hindwing, differing in size. — **virudha** *Fruhst.* (80 d), of which we figure the upper surface, is the largest race. The underside only differs in five obliquely placed, small white subapical dots on the forewing, 3 pairs of white subterminal patches in the middle of the wing and the light violet cell-spot and discal dots of both wings, which are arranged as in *climena*. Dammer. — **compta** *Röb.*, described from a ♀ from Timor-Laut, is somewhat smaller, but has still more extended and purer white markings on the upper surface of both wings. Very rare on Timor-Laut, where according to the collec-

virudha. *compta.*

eucompta. tor Rouyer the natives asked 20 Dutch florins for each example. — **eucompta** *Fruhst.* completely resembles *adorabilis* on the forewing above, except that the wing is narrower and the subapical white area less sharply defined. The white transverse band of the hindwing less developed than in *compta*, the three subanal white patches of the forewing absent. Beneath the violet discal dots are much less developed. Babber, very rare; only 2 ♂♂ in coll. Fruhstorfer.

eboraci. **E. eboraci** *Gr.-Sm.*, described from New Pomerania and New Lauenburg, is a very rare species, which is unknown to me in nature; forewing brown with a submarginal row of four indistinct bluish white dots before the apex. Hindwing with a large patch before the apex of the cell and with a curved series of seven similar transcellular spots and a submarginal row of small whitish dots, which decrease from the costal margin to the anal angle.

lacon. **E. lacon** *Gr.-Sm.*, likewise recorded from New Pomerania, is said to be darker brown than the preceding, forewing suffused with purple and bearing purple spots before the apex. The under surface very similar to *eboraci*, with larger spots than on the upperside.

malaguna. **E. malaguna** *Ribbe*, judging from a figure of Pagenstecher's, is allied to *doretta*, and is a small, very rare species, distinguished by blue reflection on the upper surface. Beneath darker than *doretta*, with the antemarginal row of dots wanting. From the interior of New Pomerania.

oceanis. **E. oceanis** *Doh.* (81 c), of which its author says that it is difficult to place systematically, has no near allies either in the Macromalayan or the Micromalayan region. In the disc of the forewing above there are sometimes obscure grey-violet patches, which are absent in the ♂ figured. ♀ of light brown instead of black colour, with a row of six elongate, pointed, whitish violet transcellular streaks and a costal streak. On the hindwing the markings of the underside show through. The latter is copiously spotted with white, both wings bear two rows of white submarginal patches and a punctiform spot before the apex of the cell. Engano.

honesta. **E. honesta** *Btlr.*, described from the Solomons without more exact locality, somewhat resembles *oceanis* in habitus, but the dark brown forewing bears two violet stripes above the submedian, a large whitish violet spot before the apex of the cell and 5—6 discal patches of the same colour, of which some are elongated and some rounded. Hindwing above without markings, but beneath as the forewing, only adorned with
faisina. light blue patches. — **faisina** *Ribbe*, from Bougainville, is a race in which the hindwing becomes somewhat lighter distally. Markings as in *honesta*, only somewhat more pronounced in the ♀♀.

E. spiculifera closely resembles *pydna* (80 c) and is one of the rarest species of *Euploea*. Four island
dromius. forms are known: **dromius** *Gr.-Sm.*, from Halmaheira, according to its author with a white spot before the apex of the cell, three white spots beyond the cell, a costal dot and two minute subapical dots. Hindwing likewise
pydna. with cell-patch and 5 patches beyond the cell. — **pydna** *Fruhst.* differs from *spiculifera Moore* from Amboina in its smaller size, its darker wings and the lighter violet-white dots on the forewing. *pydna*, however, has only 1—2 white apical dots, but no submarginal dots. The under surface on the other hand is much more copiously dotted on the disc of both wings. The hindwing bears a double submarginal row of white dots and also 5 small white circumcellular spots. In addition a distinct submarginal row of violet-white dots traverses the entire forewing. ♀: before the apex of the cell a very broad white dot; above the cell 2 white costal streaks, beyond the cell 1 white streak and 1 round dot. Further a submarginal row of 5 white dots, of which the middle ones between the radials are scarcely visible. On the hindwing 3 obsolete white dots. Under surface as above, but all the spots much enlarged; in addition there is a double submarginal row of violet-white dots.
spiculifera. Obi, very rare. — **spiculifera** *Moore* (on pl. 80 c as *pydna*) differs from *pydna* in its larger size, a very large whitish patch before the end of the cell on the forewing and in the submarginal spots, which as a rule stand
praxithea. out even more than in the figure. Apparently very rare, on Buru. — **praxithea** *Fruhst.* is a form from the South Moluccas, which in size is intermediate between *pydna* and *spiculifera* and only shows very small cell- and submarginal dots on the forewing; but beneath *praxithea* is distinct from the two previous subspecies in the entire absence of dots on the hindwing. Amboina, only 2 ♂♂ in coll. Fruhstorfer.

radica. **E. radica** *Fruhst.* I possess no *Euploea* from the Moluccas with which I could compare this species; it most nearly approaches *honesta Btlr.* from the Solomon Islands. The under surface resembles *Stictoploea* in having a submarginal, lighter brown area. The species is easily described, the upperside being entirely black with a lighter costal area on the hindwing. Under surface: forewing with a white spot before the end of the cell and 3 circumcellular, whitish spots, of which the upper two are round and somewhat violet and the lower one oblong and more yellowish. Hindwing with a violet dot before the end of the cell and 6 small violet circumcellular patches. The basal part of both wings is black. The forewing is costally and anally light brown and the hindwing, as already mentioned, is characterized by a light submarginal area. The ♀ is as the ♂, ex-

cept that there is a long white streak on the underside of the forewing between the 3rd median vein and the submedian. Obi, only 2 ♂♂ and 1 ♀ known.

E. leachi, a very interesting species, hitherto only known from Celebes, where it occurs in two local races. — **leachi** *Fldr.* (86 c), in the south of the island, taken by me at the waterfall of Maros in November, *leachi.* has the upper surface of the ♂ entirely black, whilst the ♀ is basally dark and distally light brown, and bears a row of distinct white submarginal spots and an inconspicuous row of small antemarginal dots on both wings. The under surface, which is figured, is still more copiously decorated with white. On the underside of the ♂ all the punctiform spots of the ♀ are strikingly reduced, only in the median area a series of brown, only slightly indicated intraneural patches, placed in pairs, is noticeable. — **coracina** *Hpffr.* is a smaller race, similarly *coracina.* spotted beneath, which above is easily recognizable by a row of small but strongly expressed white submarginal dots. Central Celebes, flying in August-September; North Celebes. Dr. Martin's collector found the species also in the eastern part of the island. — **albiplagiata** *Fruhst.*, from Bangkai, scarcely differs in size from *albiplagiata.* *coracina*, but bears above indistinct white dots; ♀, however, differing considerably in the very large, long ultracellular patches of the forewing and in having the white spots on the hindwing beneath nearly twice as large.

E. latefasciata *Weym.* (= ribbei *Röb.*), one of the most beautiful Euploeids, which can best be com- *latefasciata.* pared with *eupator Hew.* (80 a), as the ♀ of which Hewitson regarded and figured it. Differs from *eupator* in having narrower but longer wings, the inner margin not concave, and two oblong cell-spots on the forewing. The transcellular patches of the forewing distally more pointed, those of the hindwing almost twice as broad. The species is known from the whole of Celebes, but is everywhere of great rarity; I myself met with it both in the coast-forest near Toli-Toli in the north and at the peak of Bonthain at 1000 m in the south of the island.

E. moorei is a Macromalayan species, which is yet to be discovered on the Malay Peninsula and Java, but has already been brought to Europe from Borneo, Sumatra and its satellite islands. — **brookei** *Moore* (86 d), *brookei.* described from Sarawak, is one of the commonest species of South-Eastern Borneo and has also been repeatedly taken in the northern part of the island. The ♀ differs from the figured ♂ in the presence of a white cell-dot and of one or two transcellular dots placed between the median veins. Valve distally concave, with long, thick, shaggy hair and broad, obtuse ventral projection, which is distally likewise slightly arched. — **moorei** *moorei.* *Btlr.*, very common in North-Eastern Sumatra, I have never had from the western part of the island. ♂, but especially the ♀, as a rule with more complete and more pronounced spots on the forewing and apparently altogether lighter brown than Borneo examples. — **morrisi** *Hag.*, an island form which is still very rare, des- *morrisi.* cribed from Mentawej. Most examples have the forewing unicolorous brown and on the hindwing a more or less complete and distinct row of small submarginal and marginal spots. Under surface similar to *moorei*, but with the white spots reduced to dots. — **thiemei** *Fruhst.*, described from a ♂ in coll. Thieme in Berlin, must *thiemei.* be regarded as the most copiously white-marked race yet known. It approaches *moorei Btlr.* from Sumatra, from which it differs in its smaller size, the more prominent white submarginal dots of the forewing, and the more complete row of submarginal spots, of which the upper 3 are scarcely any smaller than in *moorei*, whilst the 4 following are considerably larger. Beyond the cell are placed 7 white streaks and dots, of which in *moorei* only one between median 1 and median 3 is occasionally present. In addition there is another rather large white dot before the apex of the cell and between median 3 and the submedian is placed a white streak. The upper surface of the hindwing is less copiously decorated than in *moorei*. There are only 3 admarginal and 3 submarginal dots present, whilst the anal row is absent above and only shows through slightly from beneath. The under surface again approaches *moorei*. But the admarginal dots are here also more prominent and beyond the cell are placed 6 white dots and streaks, whilst in *moorei* occasionally only 3, of a violet colour, are present. The underside of the hindwing differs from the upperside in a complete admarginal row of white dots, which agrees with *moorei*. Also the circumcellular dots are as in *moorei*, but white instead of violet. It is singular that *thiemei* has little in common with *morrisi Hag.* from Mentawej; for *morrisi* has the upperside of the wings entirely black and the dots on the underside of the forewing are more obsolete, whilst on the other hand the submarginal row on the hindwing is more complete. Nias.

E. crameri is one of the richest in forms of the species of the Indo-Malayan region and its satellite islands. To the east it extends as far as Bali. Valve less incurved, with straighter and somewhat more pointed ventral process than in *moorei*. — **nicevillei** *Moore*, described from the Sunderbunds, small, flat, alluvial is- *nicevillei.* lands at the estuary of the Ganges, was probably originally only accidentally introduced by shipping. It is distinguished by the unusually broad and pure white submarginal spots on both wings. Only one ♀ is yet known, which is in the British Museum collection. — **frauenfeldi** *Fldr.* (= esperi *Fldr.*, biseriata *Moore*) differs con- *frauenfeldi.* siderably from *nicevillei* in the much reduced white spots, in the ♂♂ even the proximal row of submarginal dots is sometimes entirely absent. Nicobars. — **bremeri** *Fldr.* (♀ = olivacea *Moore*) is distinguished from the *bremeri.* figured *heylaertsi* by the lighter brown ground-colour, the narrower shape and the more pronounced white markings on the forewing. Not rare in Upper Tenasserim, this form extends northward to Akyab and is also to

marsdeni. be met with in abundance in the Mergui Archipelago from December to March. — **marsdeni** *Moore* is the form from the Malay Peninsula, which as a rule has the white spots of the forewing somewhat reduced and forms *heylaertsi.* the transition from *bremeri* to *heylaertsi.* — **heylaertsi** *Moore* (86 d) is considered one of the commonest species of Sumatra, where it ascends from the alluvial plains to about 500 m and even flies about in village gardens. According to Martin examples sometimes occur which show a short, but occasionally even a distinct *niasica.* and longer sexual stripe on the forewing. — **niasica** *Moore* is smaller than *heylaertsi* and in consequence all the white markings of the ♂♂ are also reduced. On the other hand in the ♀♀ there is a supplementary row of narrow, partly violet transcellular spots on the forewing, which are wanting in *heylaertsi.* But at the same time *nagasena.* the rows of white dots on the upperside of the hindwing are entirely suppressed. Nias, very common. — **nagasena** *Fruhst.* (82 b). Intermediate between *niasica Moore* and *mentavica Hagen*, differing considerably from both, but approximating more to the Nias race. *nagasena* differs from *niasica* in the much smaller white dots on both wings, whilst apart from the shape of the wings it has only the scheme of markings on the forewing in common with *mentavica. nagasena* bears 2 complete submarginal rows of white dots on the forewing, of which the dots of the admarginal row are all of equal size and are united into 6 pairs, while the proximal row is more concave and consists only of 7 small, widely separated spots, of which the second subapical patch, resembling a pin's head, is the largest. In the median part near the costal margin there are further some obsolete dots, otherwise the deep black forewing is without markings above. On the under surface all these dots are reproduced, and in addition there is on both wings a row of small ultracellular dots, of which in the type *mentavica.* the forewing shows 7, the hindwing 8. — In **mentavica** *Hag.* some of the white dots on the upper surface disappear, only 3 remaining on the forewing in the ♂. On the other hand the proximal submarginal row of the hindwing extends above and beneath from the costal margin to the anal angle, instead of terminating before the middle of the wing, as in *nagasena.* Mentawej Islands. — On Engano no *crameri*-race has yet been observed. *tenggerensis.* — **tenggerensis** *Fruhst.*, a rare form of Eastern Java, is essentially modified, a true product of a district with pronounced dry season, pale brown, with a few scattered large white rounded patches of unequal size, which are arranged similarly as in *nagasena.* ♀ with the usual spots before the apex of the cell, a row of 7 discal, 9 submarginal and 9—11 antemarginal dots on the forewing. Hindwing without cell-patch and with abbreviated median row of white dots, all of which are inclined to bluish on the under surface. Valve smaller than *pagen-* in *crameri*, distally scarcely concave, with sharper vertral point. Tengger Mountains at 500 —800 m. — *stecheri.* **pagenstecheri** *Hag.* as a rule bears on a deep black ground only 3—4 well developed subapical patches of unequal size, a small dot in the costal margin and only very rarely small discal dots. Only the ♀ shows the spot usually found in *crameri* before the apex of the cell in the forewing and 1—2 median patches. Bawean. not rare. *singaradha.* — **singaradha** *Fruhst.*, from Bali, approximates closely to *crameri* from Borneo, with which it shows much more analogy than with the subspecies from Bawean and Java. Forewing always with distinct large submarginal spots, continued to the lower median, and particularly in the ♀ with extended, wedge-shaped median *crameri.* patches. Like all the Bali butterflies *singaradha* is only of very small size. — **crameri** *Luc.* (= johanna *Kirby*) is next to *pagenstecheri* the melanotic extreme of the species with the white spots of the forewing reduced and as a rule with the rows of dots on the upperside of the hindwing entirely absent. Valve somewhat less robustly built than in *heylaertsi.* Distributed over the whole of Borneo with the exception of the extreme *pryeri.* north. — From there **pryeri** *Moore* is known, which again recalls *heylaertsi* by the larger amount of white, *daatensis.* but is as a rule smaller and with the subapical patches somewhat more rounded. Sandakan. — **daatensis** *Moore* is said to differ from *crameri* in the relatively broader and larger subapical spots and in an almost complete row of antemarginal dots on the forewing. Hindwing likewise with distinct rows of white dots. Island of Daat, *labuana.* North Borneo. — **labuana** *Moore* approaches *pryeri* in having 2 rows of small white submarginal dots on the *lanista.* hindwing. Island of Labuan, North Borneo. — **lanista** *Fruhst.*, from Natuna, differs from *crameri* in the more profuse dotting of both wings and is intermediate between *crameri* and *pryeri Moore.* The ♂♂ bear an admarginal row of 7 small white spots and a submarginal row of 8 very much larger white spots of unequal size; there is likewise a costal spot beyond the cell and a small white dot between the 2nd and 3rd median veins. The hindwing bears on the upper surface 2 complete rows of small white dots, while in *crameri* these are either entirely absent or only one row is visible, especially in South Bornean specimens. The under surface is likewise more copiously dotted and differs from *crameri* in the double row of white dots on the hindwing. The ♀ may be easily distinguished from that of *crameri* by the presence of larger admarginal dots; the 3 discal dots are also much more prominent than in *crameri.* On the upperside of the hindwing the inner submarginal row is not so strongly developed as in *pryeri*-♀, but on the underside again complete.

malayica. **E. malayica**, a typical Macromalayan species, of which we figure the commonest branch-race, **malayica** *Btlr.* (80 b). The ♂ is deep black-brown with considerably smaller submarginal dots and mostly with the cell-spot and median patches much reduced. The ♀♀ as a rule bear on the hindwing above only a mostly incomplete row of white submarginal dots. *malayica* inhabits the true tropical forests, but nowhere ascends above the lowlands; it is fond of sailing about at a good height over small clearings and is found all the year round, *stolli.* but without occurring in great abundance. Malay Peninsula, North-East and South-West Sumatra. — **stolli** *Weym.* inhabits Nias and is inferior to *malayica* in size and consequently also in the development of the white

median and marginal spots. ♀ beneath light coffee-brown with darker marginal area, slightly tinged with violet. — **hypanis** *nom. nov.* for the preoccupied *ochsenheimeri Moore* I propose for the Javan subspecies, with still smaller expanse, above dark silky brown, with very small white marginal and discal patches. The former are repeated in more strongly expressed and more complete rows on the under surface. Java, very rare, not met with there by me. — **scudderi** *Btlr.* as a rule surpasses *malayica* in size, but has a melanotic appearance on account of the much reduced white spots, which in ♂♂ from South-East Borneo are sometimes entirely absent above. Borneo. — **claudina** *Stgr.*, from Palawan, differs essentially from all the allied island forms in the brilliant blue iridescence of the upperside and the much enlarged, pure white patches, which on the hindwing are elongate instead of rounded. *hypanis.* *scudderi.* *claudina.*

E. cratis *Btlr.*, an extremely rare species, hitherto only found at Cape Engano on Luzon and on the Babuyanes Islands to the north of Luzon. The markings are similar to those of *suluana* (84 d), but there are in addition a large crescent-shaped cell-spot and 4 yellowish circumcellular patches on the forewing. Submarginal spots, particularly between the median veins, large, heart-shaped, the discal row of the hindwing extending from the costal towards the anal margin and gradually increasing in length. *cratis.*

E. modesta *Btlr.* (= cupreipennis *Moore*, tavoyana *Moore*, mouhoti *Moore*) may be called one of the characteristic butterflies of Further India. *modesta* is by far the commonest *Euploea* of Central Siam, where I met with it in many thousands in January and February. Even on the railway from Bangkok to Korat, where the first hills rise from the rice-covered plains, they occur in perfect clouds, mixed with Pierids and all flying off together in confusion when frightened by the engine. Also when the woods were crossed they appeared in hundreds from their hiding-places in the thickets. Until the middle of February I found exclusively worn examples, but then (simultaneously with *Pap. tavoyanus*) the first generation began to emerge, which with its intensive and wonderful blue reflection on the violet-brown wings (when worn copper-coloured!) does not justify the name *modesta*. From the relatively short scent-pencils, which are projected with difficulty, the species emits an extremely agreeable odour. Though varying much in size (forewing 38—45 mm in length), it is very constant in markings. It resembles a miniature *camaralzaman* (79 c). Tenasserim to South Annam, Cambodja, Island of Salanga. — **buxtoni** *Moore* (81 b) is a much darkened race, whose occurrence on Sumatra has hitherto been doubted. I have, however, received 5—8 examples from the neighbourhood of Padang Pandjang in the western part of the island. The wings are still darker than in Siam ♂♂ and have not such beautiful blue reflection, the white double row of submarginal dots on the hindwing somewhat reduced. — **lorzae** *Moore* apparently replaces the species in North Borneo, unknown to me in nature, according to its author's figure it bears 3 moderately large, wedge-shaped white subapical spots on the forewing. *modesta.* *buxtoni.* *lorzae.*

E. cameralzaman *Btlr.* (79 c) is not only one of the largest and most beautiful Euploeas, but also one of the most pleasant-scented butterflies of South Asia, the ♂♂ emitting a very ageeable, sweet scent of vanilla. According to my observations the butterfly always traverses the forest-shades singly at about 2—3 m. above the ground and only during the morning, and is always very rare; seen from a distance it recalls South American Morphids. It was not possible in the figure to reproduce the wonderful blue gloss which overspreads the proximal $^2/_3$ of the wings. The type came from Chentabun, Siam; taken by me at the Muoklek River in January-February, it has recently been discovered also in South Tenasserim. — A ♀-form with a third row of white dots in the middle of the hindwing has been described by Moore as **carpenteri** from the islands of the Mergui Archipelago. *cameralzaman.* *carpenteri.*

E. deheeri *Doh.* inhabits the most westerly islands of Micromalayana. The name-type came from Sumbawa. It may best be compared with *werneri* (86 d), from which it is easy to distinguish by the absence of all the median markings of the forewing and almost all the submarginal dots of the hindwing. The underside of the hindwing is characterized by a yellowish belt with blue-white patches, which are absent in *werneri*. — **suavissima** *Fruhst.* is based on a series of examples with elongate white streaks, often somewhat tinged with violet, on the hindwing, which recall *cratis* from the Philippines. Submarginal patches of the forewing above mostly violet. Lombok, at 5—700 m, not very rare, April-June. — **salinator** *Fruhst.*, from Alor, differs in the rounded, whitish violet submarginal spots on the forewing above, which are more than twice as large, and in the much darkened under surface, whose white dots are all smaller. — Finally, **lamos** *Fruhst.* is a very rare race from East Java. ♂: forewing dark brown with intensive blue-violet sheen, a row of 8 large, pure white submarginal patches, arranged as in *werneri* (86 c), 4 indistinct, partially violet transcellular spots and the usual costal and cell-spot. Hindwing lighter brown, especially distally, with only one row of 4 distinct submarginal dots. Under surface with the broad violet streak at the submedian, which is always absent in *crameri*-♂♂, but as a rule is present in *deheeri*. Hindwing without the yellowish pale median area which *deheeri* and *suavissima* have in common, in this respect forming a transition to the remarkable Flores race. — **kuehni** *deheeri.* *suavissima.* *salinator.* *lamos.* *kuehni.*

Röb., from Flores, shows a striking resemblance to *werneri*, but the pattern of the upperside corresponds to that of *lamos*, on the other hand the much broadened white patches on the hindwing beneath agree more with *werneri* than *deheeri*. Doubtless rare, only one pair as yet known.

werneri. **E. werneri** *Fruhst.* (86 d). On the small Vulcan Island, only 20 km from German New Guinea, the Swiss botanist Dr. Eugen Werner has discovered a species of *Euploea* which has not hitherto been observed on the main island. This interesting new species approaches *deheeri Doh.* from Sumbawa, *suavissima Fruhst.* from Lombok and *lamos Fruhst.* from East Java, but differs from them all in the larger white submarginal spots of the forewing, the presence of a row of white patches on the hindwing and a circumcellular group of 5 smaller white dots on the forewing. In the cell of the forewing, before the apex, is placed a further large white dot. In the ♀ all these white spots are essentially larger and more distinct and along the submedian runs an oblong white transverse streak, which occasionally occurs in the ♂ also. Under surface black without the light patch on the hindwing so characteristic of *deheeri*. On the hindwing there are likewise 6—7 transcellular white spots and the apical dot before the end of the cell. The figure (86 d) renders a further description superfluous. The relationship with *deheeri* is revealed in the genitalia, but the valve has a more regular, less distinctly rounded form, which recalls a bird's head; its ventral process is somewhat more sharply constricted and the distal end more pointed.

batesi. **E. batesi**, originally described from Halmaheira, is an exclusively Papuan species. I have no examples which agree with the name-type, **batesi** *Fldr.*, compared by its author with *melina Godt.* They closely ap-
pinaria. proach the island race **pinaria** *subsp. nov.* figured as *batesi* (86 c), which differs from all its allies in having the distal margin of both wings nearly grey-yellow, especially in the ♀. ♂: occasionally with two small violet subapical spots on the forewing, otherwise like the ♀ absolutely without markings. Forewing with a cell-dot and two intramedian dots, hindwing the same, but with six circumcellular dots suffused with violet. Marginal
mimica. area of the hindwing whitish. Waigeu, very rare. — **mimica** *subsp. nov.* somewhat surpasses *pinaria* in size, the ground-colour darkened, the distal margins more red than yellow-brown and the basal colou-
publilia. ring of the hindwing beneath decidedly red-brown. Dutch New Guinea, Sorong. — **publilia** *subsp. nov.* is a relatively small race, above almost black-brown, marginal area of the hindwing much darken ed, with distinct, black distal margin, basal area of the hindwing beneath dark coffee-brown, with strikingly broad, light yellowish border which extends far along the inner margin and is sometimes suffused with white, sometimes with violet. German New Guinea, occurring in great abundance at the Astrolabe Bay.

nubaida. **E. nubaida** *Gr.-Sm.*, described from Halmaheira and unknown to me in nature, is according to its author a larger species and differs chiefly in the absence of any pale distal area on both wings. Ground-colour velvety brown with paler costal margin to the hindwing.

E. wallacei exclusively inhabits the Moluccas and forms, as its author pointed out, a group by itself
gilda. on account of its long, uniformly narrow wings. — **gilda** *Fruhst.* (82 e ♂, 86 c ♀, on the plate misprinted ♂) differs from *wallacei* from Batjan in the lighter yellow-brown discal part of both wings and in the much enlarged white submarginal spots of the forewing. The under surface is darker, but as above the white patches stand
ares. out more strongly than in the Batjan race. Obi. — **ares** *Fruhst.* forms a connecting-link between *wallacei* and *gilda*, being lighter in the discal part than *wallacei*, but somewhat darker than *gilda*. The white dotting is likewise intermediate; on the other hand both wings are beneath even more copiously spotted with white than in *gilda*. Buru, Miro, time of flight November. Must be very rare on Buru, as
wallacei. Doherty has not taken it there. — **wallacei** *Fldr.*, the name-type, considerably surpasses *gilda* and *ares* in size, its upper surface is dark brown throughout, with appreciably lighter middle of the wings and in the ♂♂ as a rule wit hout white submarginal dots, which in the ♀♀ are occasionally slightly indicated. Batjan, Halmaheira, Morotai.

E. confusa forms the natural continuation of the preceding species in the Papuan region and it is not
grayi. impossible that it should even be specifically united with it. — **grayi** *Fldr.* (82 e), above and beneath dark brown, with yellow-brown disc in the ♂♂ and light yellow, distally even whitish area in the ♀♀. In the latter the lighter area of the forewing even encroaches into the cell. Most ♀♀ are above much lighter than the ex-
faunia. ample figured. Aru. — **faunia** *subsp. nov.* differs from *grayi* in the much narrower (scarcely entering the cell), but much longer yellowish area of the forewing in the ♀♀, and in the much darker ♂♂, in which the discal part
confusa. is almost red-brown. Dutch New Guinea, Sorong. — **confusa** *Bilr.* (= waigensis *Stgr.*), described from Waigeu,

is characterized by lighter brown ground-colour and the ♀♀ show a light violet median area, which is sometimes much widened, two examples even having the cell and the apical part of the forewing also suffused with violet. Only in *confusa* the blue circumcellular patches on the underside of the hindwing are distinct. — **melia** *Fruhst.*, from Fergusson Island, differs from *confusa* from Waigeu in the dark, almost black-brown ground- *melia.* colour of both wings, which is especially pronounced beneath. The light discal spot of the forewing peculiar to *confusa* is much widened in *melia* and continues about equally broad nearly to the distal margin. This spot is in *confusa* whitish violet, in *melia* basally reddish brown, becoming yellowish white distally. — **catana** *catana.* *Fruhst.* (81a) differs from *melia* in the unicolorous, dark red-brown discal area of the forewing, which particularly in the ♀♀ from German New Guinea occupies also the lower half of the cell. The hindwing is quite as dark as in *melia,* but differs from it in having a much lighter, coffee-brown anal area on the upperside. German and British New Guinea. According to Hagen occurring not very rarely in the rainy season. — **japudia** *subsp. nov.* was only recently discovered, on the occasion of the advance of the Dutch expedition to *japudia.* the snow-mountains of above 4500 m in the southern part of Dutch New Guinea. Both sexes of the new race may be recognized by a strikingly light and much broadened yellowish white median area on the forewing, which in the ♀ extends to far beyond the middle of the cell. Under surface of the hindwing without a trace of violet or blue discal patches.

E. alecto (= melancholia *Btlr.*), a Papuan species, which is distributed westwards to the Moluccas and southwards to Australia and is divided into several local forms, some of which are highly specialized. **alecto** *alecto.* *Btlr.*, the first described subspecies, inhabits Amboina and the Southern Moluccas. Both sexes are easy to distinguish from the figured *barsine* (82b) by the presence on the hindwing of two rows of smaller submarginal spots, lightly scaled with brown. On the under surface in the middle of each wing are five rather large violet patches of different sizes bordering the cell. The forewing of the ♂♂ frequently bears further a row of subapical and that of the ♀♀ always a row of subterminal dots. — **zodica** *Fruhst.* ♂ differs from *zodica.* *nox* from the Aru Islands and *alecto* from the South Moluccas in the entirely black forewing with no dots and on the hindwing in having the white dots at the distal margin almost suppressed. Under surface: forewing similiar to **alecto**, but with smaller costal and discal spot. The hindwing bears likewise smaller discal and marginal dots. Obi, very rare, only 1 ♂ known. — **nox** *Btlr.* approaches *barsine* above and is distinguished *nox.* by 4 or 5 distinct white subapical patches on the forewing and small submarginál dots on the hindwing. The small violet discal spots on the underside of the wings even smaller than in *zodica*. On the Aru Islands, apparently very scarce. — **diadema** *Moore* is a subspecies especially copiously spotted with white, the subapical *diadema.* spots of the hindwing even more strongly expressed than in *nox,* hindwing always with two rows of white submarginal patches, of which the proximal one is composed of especially large, rounded oval interneural areas. The forewing of the ♀♀ bears in addition a bordering of small antemarginal dots. On the other hand almost all the small cell-spots and transcellular spots on the under surface are absent. British New Guinea, flying in January. — **barsine** *Fruhst.* (82b). ♂ differing from *diadema* from British New Guinea in a prolonged row *barsine* of submarginal spots on the forewing, which are only about $^1/_5$ as large as those of *diadema*. The hindwing bears only one row of white patches, which are larger and more rounded than in *diadema*. The marginal row of white dots is entirely absent in the ♂. The underside of the forewing is without dots and on the hindwing there is likewise only a submarginal row of white spots. Fergusson, rare. — **monilifera** *Moore* is *monilifera.* an unimportant, somewhat darkened form of *diadema*, based on a ♀ from Thursday Island. — **misagenes** *misagenes.* *subsp. nov.* is velvety brown, distally a little lighter, with a submarginal row of nine white spots, curved before the apex, of which the first three, placed almost parallel to the costal margin, are the smallest and the fourth is the largest; posteriorly they decrease again in size; the last is double behind the lower median. Hindwing with a submarginal row of white spots beginning at the anal angle, the posterior ones elongate-oval, the upper ones rounded and more isolated. A complete row of white marginal dots, which is repeated on the under surface. (Hagen). Described from a ♂ from Dampier Island.

E. eichhorni *Stgr.* (= boreas *Misk.*) (81c), a magnificent form, which replaces *alecto* in Australia and *eichhorni.* is probably a good species. Upper surface deep velvety black. Beneath as above, but with brown apical area on the forewing and the hindwing light brown throughout. Forewing with violet streak at the median and the normal blue discal spots of *alecto*, but more prominent. According to Waterhouse *boreas Misk.* is a synonym of *eichhorni.* North Australia, Queensland.

E. ebenina *Btlr.*, very nearly approaching *alecto nox Btlr.*, but at once distinguishable by the intensive *ebenina.* blue reflection on the upper surface of the wings. The concave row of white subapical patches is prolonged to the submedian, the hindwing as in *diadema* bears two rows of white marginal spots, the proximal row consisting of larger oval spots, the distal of mere dots. The dots on the under surface appear to vary according to the sex. The ♂ bears no discal spots at all, the ♀ extremely pronounced violet cell-spot and 5 or 6 transcellular spots. Aru, apparently very sparingly. — **nymphas** *subsp. nov.* differs from *ebenina* in the presence of *nymphas.*

supplementary white median dots and a fine streak along the submedian of the forewing. All the submarginal dots smaller, but purer white, those of the under surface more delicate and lighter violet than in *ebenina*. Key Islands, only one ♀ in coll. Fruhstorfer.

E. **æthiops**, a typical Papuan species, which does not extend beyond New Guinea and the neighbouring islands, affords a conspicuous example of the variability of a species on the main island itself, since it pro-
aethiops. duces as many as 5 easily distinguished local races. **æthiops** *Btlr.* (86d), the name-type, was described from Waigeu and like all the representative races is characterized by a scent-spot with dull silky gloss which extends beyond the cell of the hindwing and surpasses even that of *alecto* in its long, shaggy androconia. Under surface of the forewing with a long white stripe over the submedian and 3 whitish violet discal dots. Hindwing with a row of 7 small circumcellular and 10—11 subterminal spots. Hindmargin of the ♂♂ light
tamis. yellow-brown, that of the ♀♀ grey-brown. — **tamis** *subsp. nov.* inhabits Sorong in Dutch North-West New Guinea. Hindwing of the ♂ with darker marginal area, that of the ♀ gradually fading into the light brown
latreilli. ground-colour, subterminal dots present on the underside of both wings. — **latreilli** *Kirsch.* (= reaumuri *Oberth.*) was recorded by both authors as coming from Dorey; it is the darkest of the known forms and probably also the largest. ♀ above deep black-brown with bright dark violet gloss, the marginal area scarcely lighter.
melinda. Also found by Doherty at the foot of the Arfak Mountains. — **melinda** *Gr.-Sm.*, erected on a single ♀, seems to me to be a form with a row of white spots on each wing, such as I have before me from Waigeu, but considering the similarity of the Euploeid-♀♀ from New Guinea, even of those which belong to quite different groups, it is imposible to say anything with certainty without having seen the type. Without exact locality,
lygdania. perhaps Humboldt Bay. — **lygdania** *subsp. nov.*, somewhat smaller than *latreilli*. Both sexes beneath even darker,
pheres. with more delicate violet discal spot on both wings. Mefor. — **pheres** *subsp. nov.* inhabits the island of Jobi in Geelvink Bay; it is always reduced in size, hindwing only inappreciably lighter even in the anal angle, beneath in the basal area also with bright blue gloss. All the violet markings, and also the streak along the
coffea. submedian vein, much abbreviated and reduced. — **coffea** *Fruhst.* (86e) is the most brightly coloured local race of the main island, ♂ with distinctly defined, light colfee-brown anal margin to the hindwing. Upper surface, ♀ mostly with brilliant violet costal margin and sometimes even with the marginal area of the hindwing variegated with white. Occasionally the apical and distal area of the forewing is grey-brown, and beneath
occulta. with violet mealy powdering. German New Guinea, very common near Friedrich-Wilhelmshafen. — **occulta** *Btlr.*, in contrast to *coffea* with dark brown distal margining to the wings, which also beneath is confined to a narrow area. *occulta* again approaches *latreilli*, from which, however, it is easy to distinguish by the shorter and more rounded wings, especially in the ♀♀. British New Guinea, Collingwood Bay, type from Pt. Moresby.
monaeses. — **monaeses** *subsp. nov.* was likewise discovered on the expedition of Nouhuis and Lorentz already mentioned. The ♂ differs from all the allied forms from New Guinea in the pale yellow-brown anal area of the hindwing above and the yellow-brown instead of reddish marginal area of both wings. The ♀ approaches that of *melinda* and bears three white subapical patches on the forewing and a row of distinct yellowish submarginal spots on the hindwing, and the anal part of the hindwing is almost pure white. Under surface lighter brown than in other *æthiops*, distal margin of the hindwing yellowish white. South-West Dutch New Guinea.

obscura. E. **obscura** *Pagenst.*, judging from a figure in Iris (1898, pl. 4, f. 2), is either a local race of *æthiops* or a nearly allied species which represents *aethiops* in the Bismarck Archipelago. Shape apparently agreeing with *pheres* from Jobi, but the scent-spot on the hindwing only extends to the middle of the cell; forewing beneath with a submarginal row of small white dots and three similar dots grouped round the cell. Cell of the forewing itself without white patch before the apex, which, however, is frequently absent also in *aethiops*. New Lauenburg, New Pomerania.

cerberus. E. **cerberus** *Btlr.* (81c), of reddish brown ground-colour with slight bronzy reflection on the forewing, which sometimes bears a row of 5 submarginal dots. Beneath exactly as in *obscura*, but with distinct violet dot before the end of the cell of the forewing, on the other hand the white patch along the subcostal of the
subpunctata hindwing is absent. New Pomerania, New Lauenburg, common, varying slightly. — **subpunctata** *subsp. nov.* is a smaller darkened form with more distinct bronzy reflection on the forewing and much reduced whitish violet dots on the underside of both wings. Especially striking is the reduction of the white spot between the middle and lower median vein on the forewing. New Mecklenburg.

E. **resarta** (82b) is one of the most interesting of the known species, exclusively confined to the east of New Guinea, and apparently not yet observed in the Dutch part of the island. There are two local races
turbonia. to be mentioned. **turbonia** *subsp. nov.* is the form figured and occurs in Kaiser-Wilhelmsland, but only at Finschhafen and Simbang and is very rare. Under surface as above. Forewing with a blue dot before the discocellular, a white wedge-spot between the median veins and 3—4 small circumcellular streaks between the radials. Hindwing with a blue-violet cell-dot and 5 postdiscal dots. Hagen mentions examples which

are dark brown above, lighter towards the margin, and with obsolescent submarginal band on the forewing. — **resarta** *Btlr.*, first brought to Europe from Pt. Moresby, in my collection from Milne Bay, differs from *turbonia* in the essentially narrowed white wedge-spots of the forewing and the shorter proximal submarginal patches of the hindwing, which are consequently not united with the subterminal dots. *resarta.*

E. funerea *Btlr.* is a very distinct species, which varies in the increase or suppression of the white bands of both wings. Dark black-brown, costal and distal margin olive-brown with slight bronze sheen. Both wings traversed by a grey-white band broken up by the veins into separate spots, which is angled on the forewing and in the ♀ twice as broad as in the ♂. Beyond this band a row of submarginal dots, which are placed in pairs. Beneath with a blue spot in the cell of both wings, this spot on the forewing is surrounded by 3—4 and on the hindwing by 5 spots placed in an elbowed row. Pt. Moresby, British New Guinea. — **squalida** *Btlr.* Smaller, paler, the white spots smaller and hence more isolated, of darker cream-colour. Submarginal dots on the forewing absent and on the hindwing indistinct. Merely a form of the preceding, from the same locality; in the British Museum and in coll. Fruhstorfer. *funerea.* *squalida.*

E. helcita is the oldest name for a small group of Euploeas which inhabit the Oceanian islands and of which we only know a small number. Most of them present a faithful copy of convergent species, such as *eleutho* (84 d) and *schmeltzi,* and hence they are nearly always mixed with them in collections, although they differ considerably in the absence of the silky sexual stripe on the forewing. They are probably not rare in certain places, but for nearly 20 years scarcely an example has been brought to Europe from their remote islands, which is much to be regretted, as many new forms still await discovery. — **helcita** *Bdv.*, from New Caledonia, seems to approximate very nearly to the figured *aglaina.* Size of *eleutho* from Guam, upper surface brown-black, apex with 4—5 small white dots. Hindwing with a row and a half of very small dots. Under surface of the hindwing with a concave row of 7—8 violet spots, one of which is in the cell. Forewing with 5—6 dots, one of which is before the apex of the cell. — **aglaina** *subsp. nov.* (86 a) differs in having two further white median spots on the forewing and more complete rows of submarginal dots on the hindwing beneath. Tutuila, Samoa Islands. — **perryi** *Btlr.* Forewing with a large white oblong spot beyond the cell between the upper and middle medians and a row of 6—7 subapical and submarginal dots, as well as a costal dot at the point of origin of the first subcostal of the forewing. Hindwing with the usual 2 rows of small white dots. Savage or Niue Island. — **eschscholtzi** *Fldr.* is the race most strongly and conspicuously white-spotted, having a large quadrate patch beyond the cell of the forewing, an oblong rectangular spot between the medians, a distinct costal spot and 4 irregular ones. The double row of white dots on the hindwing composed of elongate, narrow speckles. Fiji Islands. — **distincta** *Btlr.* resembles the preceding, except that the white quadrate patches beyond the cell of the forewing are deeply incised distally, and the dots of the hindwing much reduced. Ellice Islands. — **intermedia** *Moore* is intermediate between *perryi* and *distincta.* Forewing with even more reduced white spots, but hindwing with a submarginal row of larger patches. Raratonga Island. **indistincta** *Moore* appears to be only an aberration of this, almost entirely without spots. Described from the same locality as the preceding. *aglaina.* *perryi.* *eschscholtzi* *distincta.* *intermedia* *indistincta.*

Subgroup b. With glossy, silky, mostly distinct sexual stripe on the forewing. *Crastia Hbn.* (1816), *Chanapa, Andasena, Deragena, Bibisana, Betanga, Penoa, Mahintha, Karadira, Pamasa, Tagata, Pramesta, Rausuma, Chirosa, Mestapra Moore* (1883).

E. core *Cr.* inhabits the whole of India south of the Himalayas and in general resembles the figure of *suluana* (84 d), but bears a shorter and narrower scent-stripe. The butterflies are found even in gardens ta Calcutta, where they flutter sluggishly from flower to flower; they are also fond of congregating in large numbers and have been observed in the harbour of Bombay crossing over the sea from one island to another, and it would be interesting to learn whether they are able to recognize or to scent out the land from a distance or whether they boldly follow their wandering instinct without any plan. – Three species of Apocynaceae and three species of Ficus are already known as food-plants of the larva. Larva always singly, sluggish, like all the other Euploeid larvae on the underside of the leaves; ground-colour yellowish with a lateral red-brown ventral stripe and some red-brown dorsal rings on each segment. Four fleshy, sometimes rolled-up reddish tentacles. Pupa short, thick with the abdomen swollen, on the first day yellowish, on the second with slight gold or silver gloss, a few days later emerald-green with brilliant metallic gloss on the head. Before emergence the colour changes into a purple-black, with a white band at each side. Pupal stage 6—9 days, probably according to the humidity of the air. The butterflies are fond of resting on wet places in the road and are commonest at Calcutta in the cold months. October to March. — **vermiculata** *Btlr.* is a larger form and ornamented with broader white bands than *core* from the plains. Originally described from the north-western Himalayas, but extending to Sikkim and Assam, sometimes reaching elevations of 2000 m. — **asela** *Moore* is a typical island race with the white patches darkened and on the forewing even gradually suppressed and the ground-colour lighter brown. — Larva adorned with narrow white and purple rings and with red and black spots: on the Indian oleander. Pupa golden yellow, with brown stripes and bands. One *core.* *vermiculata.* *asela*

of the commonest butterflies of Ceylon, occurring from the plains up to 6000 ft. and especially in November-December gathering together in large migratory swarms, which, however, never leave the island, not emigrating to the adjacent mainland. I observed them myself at the beginning of the monsoon (end of May) up to many thousands in neglected village gardens at altitudes of about 600 m. — As **graminifera** Moore has described a further race from the Malay Peninsula, unknown to me in nature, with smaller and more sharply defined white patches on the hindwing.

graminifera.

distanti.

E. distanti *Moore* (81 c) appears to replace *core* on Sumatra and is regarded as the commonest of the brown Euploeas on this island; it prefers the neighbourhood of the sea and never ascends even to slight elevations. The ground-colour varies from light to dark brown, the extent of the white spots of the hindwing is also inconstant. Malay examples appear to bear smaller submarginal dots on the hindwing. Judging from specimens in my collection the sexual streaks in the ♂♂ are occasionally wanting, but sometimes they are larger than the normal. The ♀ bears always in addition one or two white dots beyond the cell of the forewing. — **circuita** *Swinh.,* described from examples found by me in Further India, is a local form with the white patches on the forewing reduced by more than half, and in consequence widely separated. On the other hand the submarginal patches of the hindwing show a tendency to become broader. Under surface as in *distanti* with large violet spot before the discocellular and a large, pointed-oval white intramedian patch. Tonkin, Cochinchina.

circuita.

godarti

E. godarti *Luc.* (= siamensis *Fldr.*) (81 d) is one of the most variable Euploeids of South Asia and it is only to be regretted that Felder's name must sink, for *godarti* is one of the characteristic butterflies of Siam and to be met with in all parts of the country in countless profusion. I found the species also in Tonkin, and even on the storm-beaten sea-coast of South Annam and on the island of Kosi-Chang in the Gulf of Siam. Bingham sent me *godarti* also from Tenasserim and Burma, where it is nowhere rare from February to July and extends also across Tavoy on the Mergui Archipelago. Examples occur in which the white patches on the forewing are as broad again as on the figure (**dominans** *form. nov.*), and further both ♂♂ and ♀♀ with the apical area of the forewing light white-grey instead of more or less light blue-violet (**recussa** *form. nov.*) — Those individuals which show no violet or grey-white apical tinge pass as **layardi** *Druce* (= binghami *Moore,* subdita *Moore*). This form extends from Tenasserim to Tonkin and is not at all rare in Siam. — **tonkinensis** *Swinh.* is the name given to an aberration corresponding to *layardi,* from examples found by me in Siam, in which even the white costal and subapical dots of the forewing are suppressed. — Finally, **defigurata** *form. nov.* is the rarest of all the varieties. without a trace of the rows of submarginal dots on both sides of the hindwing, and with even the small subterminal spots on the underside of the forewing wanting. Upper Burma; type in my collection. — **prunosa** *Moore* appears to be a local race of *godarti* without violet tinge in the apical part of the forewing and without white submarginal dots on the hindwing above. The marginal area of both wings paler than the basal half, the sexual stripe very small. Only one example known, type from South China in coll. Oberthür.

dominans. *recussa.* *layardi* *tonkinensis.* *defigurata.* *prunosa.*

orontobates.

E. orontobates *spec. nov.* forms a transition from *godarti* to *modesta Btlr.* and *camaralzeman,* having the same shape and the large size as the latter, but the wonderful blue reflection is absent. *orontobates* differs from *godarti* in the extremely small, scarcely recognizable sexual stripe on the forewing. but a light mouse-grey scent-spot on the hindwing above, which also extends to the anterior third of the cell, submarginal patches of the hindwing as large and pure white as in *camaralzeman* and at once distinguishable from the yellowish grey ones of *godarti.* Under surface deeper black-brown than in *godarti.* Chentabun, East Siam; only 1 ♂ taken by me in January.

scherzeri.

E. scherzeri *Fldr.* is the older name for the species which passes in English museums and collections under the name *camorta Moore.* Wing-contour as in *godarti,* but somewhat more rounded. Ground-colour dark sepia-brown, distally somewhat paler. Upper surface mostly without a trace of white patches, only rarely with one or two discal and costal dots. Under surface somewhat paler than upper, a long yellowish white streak between submedian and lower median, a large cell-spot, costal and two discal spots whitish violet, hindwing with cell-patch and five transcellular patches. ♀ commonly with broad, nearly whitish brown bordering to both wings. On all the Nicobar Islands.

andamanensis.

E. andamanensis *Atkins.* is the only known *Euploea* in which the ground-colour is light grey, becoming somewhat darker distally. Markings as in *distanti,* but the ♂♂ also bear a large white spot before the apex of the cell on the forewing and two discal patches, the ♀ having three. Forewing with two widely separated rows of white submarginal spots of about equal size. Under surface lighter than above with slight yellow sheen. From March to August at Port Blair, Andamans.

E. amymome *Godt.*, very common on Hong-Kong and the adjacent mainland and very variable in size and in the arrangement of the dots on the wings; the species has received a number of names, such as *kinbergi Wallgr., lorquini Fldr., felderi Btlr.,* and through incorrect labelling of specimens has also been reported from Sumatra and Java, and even Ceylon, but it is certain that it only inhabits southern China. Recently it was discovered on Hainan. Size about the same as *heyluertsi* (86 a). Ground-colour dark brown with extremely bright violet reflection. Forewing mostly with two more or less complete submarginal rows of small white dots, rarely a cell-dot, but always with 2—3 discal dots. Hindwing mostly without submarginal spots, only one of my ♂♂ bears such (whitish sprinkled with yellow-grey scales). Under surface as in *godarti,* but as a rule with only one row of small antemarginal dots on the hindwing. — Larva probably undescribed, but known to feed on Strophanthus divergens. *amymome.*

E. haworthi *Luc.* has shared the fate of the preceding, being provided with a series of names, such as *huebneri Moore, janus Btlr., moorei Fldr., eleusina Hbn.* A faithful copy of the preceding, likewise very variable, but only with indistinct violet reflection on the upperside, moreover the submarginal patches are not so uniform as in *amymome* and the subapical spots are essentially broader. Sexual stripe longer than in *amymome.* Hindwing almost always with two rows of small yellowish white submarginal spots, under surface with violet cell- and discal patches, but rows of white submarginal dots. In my collection there are over 60 examples, of which no two are alike. Not rare in East Java at elevations of 500—700 m., the species is apparently rare in the neighbourhood of Batavia. The West Javan examples are as a rule smaller than those from the Tengger Mountains in the east of the island and one of the above names will no doubt denote the form, but which can only be proved by comparison of the type. Dr. Martin's collector has also taken it in large numbers on Bali. It is not impossible that *geyeri Fldr.* may be founded on an aberrant example of this species. — **inconspicua** *Moore.* Forewing without apical and marginal spots and with a very short, thin sexual stripe, hindwing with two rows of whitish patches, which towards the costal margin are reduced and darkened. Described from Sumatra from examples taken by Wallace; if the locality is correct it should perhaps be included as a form of *haworthi.* Should it prove to be really a local race worth naming, then the name, which is already preoccupied by Butler, must be altered. *haworthi* *inconspicua*

E. bauermanni *Röb.,* described from the small, remote island of Kabia, to the south-east of Celebes, doubtless belongs near *haworthi,* of which it presents a miniature edition. Forewing as in *haworthi,* but with a distinct series of transcellular patches on the forewing and longer wedge-shaped subapical patches. Hindwing with small marginal dots and three larger submarginal spots, only extending to the upper median. Under surface as in *haworthi,* exeept that all the white markings on the forewing are more pronounced. — **kalaona** *Fruhst.,* discovered by Everett on the island of Kalao, between Flores and Celebes, is somewhat larger than *bauermanni* (length of the forewing 36 mm.) and differs in having a broader sexual stripe. The circumcellular wedge-spots of the forewing are absent, and also all the white spots on the underside are somewhat reduced, *kalaona* thus forming a distinct transition to *haworthi,* whieh latter occurs certainly also on Flores. *bauermanni* *kalaona.*

E. alcathoë *Godt.* has apparently spread from Further India over all the Macromalayan islands and has advanced eastwards from Java to Lombok. Not very numerous on the continent and in Sumatra, it is very scarce at the extreme limit of its range. — **doubledayi** *Fldr.* is the Indian branch-race of the collective species, described from Assam, also occurring in Burma, conspicuous by its size and the extended, long white submarginal streaks of the hindwing, particularly in the ♀. The ♂ figured belongs to the dry-season form and comes from Siam, where the species has developed a local race which is especially characterized by the darker ♀♀ and has the intraneural areas of the hindwing predominantly blue-grey instead of pure white. — **aesatia** *subsp. nov.* (85 b). ♀♀ without a trace of white spots on the upperside of the forewing are especially typical, together with which examples also occur which form a transition to normal *doubledayi* in having 3 white discal dots. Siam, Lower Burma, common up to about 700 m. — **gardineri** *Fruhst.* (♀ = menetriesi *Fldr.*) is erroneously called by English authors *menetriesi Fldr.;* Felder has described under this name a local form belonging to *dione.* Both sexes are inferior in size to *aesatia,* of which they otherwise present a still more darkened extreme with shorter brown-grey intraneural patches. Malay Peninsula. — **martinus** *Fruhst.,* in contrast to the preceding provided with somewhat more distinct small white-grey spots on the hindwing, inhabits the plains and the spurs of the mountains in north-eastern Sumatra. — **vonara** *subsp. nov.* bears particularly in the ♀ strongly expressed and almost pure white and longer strigae in the submarginal area of the hindwing. Also in the ♀♀ there is a double row of white marginal dots on the upperside of the forewing. West Sumatra. — **simplex** *Fruhst.,* an essentially darkened race of small size, with abbreviated sexual stripe on the forewing and thin, indistinct striation on the upperside of the hindwing. Nias. — **pahakela** *Doh.,* the darkest of the known island races, both sexes without a trace of white striation on the hindwing, ♀ dark brown throughout with the hindwing lighter. Moreover, beneath all the submarginal white markings are absent, only the violet discal patches and a series of small marginal dots remaining, and even *doubledayi.* *aesatia.* *gardineri.* *martinus.* *vonara.* *simplex.* *pahakela.*

arasa. the latter mostly wanting. April. Engano. — **arasa** *subsp. nov.* is the form from the Mentawej Islands. It approaches *simplex* from Nias, and still preserves traces of white striation on the under surface of the hindwing, which sometimes show through above, and are lighter and more distinct the larger the examples are. —
alcathoë. **alcathoë** *Godt.* (= eyndthovi *Fldr.*), the name-type, a butterfly of elegant but simple facies. Forewing deep velvety black, hindwing lighter brown distally. Scent-stripe distinct, but narrow and somewhat raised at the edges. ♂ with almost rounded, short submarginal patches on the hindwing, which, however, in the ♀ again
geyeri. assume the normal streak-shape and stand out distinctly, the colour somewhat inclining to yellowish. **geyeri** *Fldr.*, unknown to me in nature, is probably a dry-season form of it. West and East Java. Bali. Lombok.
uniformis. but everywhere scarce. — **uniformis** *Moore* approaches *pahakela.* ♂ above without appreciable submarginal stripes, which in the ♀ show through slightly from the underside. ♂ beneath with vestigial. ♀ with two
salistra. distinct but thin grey-white longitudinal streaks. North and South Borneo. — **salistra** *subsp. nov.*, the race from the Natuna Islands, differs in the sparsely scaled but distinct grey-white, rather broad intraneural areas of the hindwing, which especially beneath are purer white and strongly expressed and are accompanied by strikingly large subterminal dots. The violet discal patches of both wings brighter and standing out more distinctly than in *gardineri*, to which *salistra* approximates more nearly than to *uniformis* from Borneo. —
distincta. Finally, **distincta** *Stgr.* is the most northerly form known, like *claudina Stgr.* more copiously decorated with white than the allied races. The rows of spots on the hindwing are purer white and more sharply defined and even on the underside of the forewing there are two rows of dots, although incomplete. Palawan. very rare. *distincta* is perhaps conspecific with the following species.

snelleni. **E. snelleni** *Moore*, previously only known from East Mindanao, I have also received in a variety from Bazilan. Above characterized by a lighter and somewhat narrower androconia streak on the hindwing, it may be recognized beneath by three light brown longitudinal stripes in the cell of the hindwing and three extremely faintly marked streaks of white-grey colour which are placed between the radials and the upper median. Two incomplete rows of rounded submarginal patches on the forewing are repeated on the upper surface. —
peducaea. **peducaea** *subsp. nov.* differs from the name-type in the smaller size, whilst the white patches and streaks o both wings are nevertheless almost twice as broad, which is noticeable both above and beneath. Also the third intraneural row of streaks on the underside of the hindwing is lighter and more sharply marked than in Mindanao examples. Pazilan. Very rare, discovered by W. Doherty in February 1898.

tobleri. **E. tobleri** *Semp.* is one of the rarest and most wonderful species of *Euploea*, apparently exclusively inhabiting the mountains and hitherto only observed on Luzon, flying in June. ♂: forewing deep black, with 4 large, quadrate white subapical spots united into a band and 6—8 blue subterminal dots. Hindwing pure white except where it is covered by a grey furry patch of androconia which extends over the entire cell, the narrow, sharply defined distal margin black, adorned with blue-white dots. Under surface of the hindwing white, only intersected by black veins, and with a submarginal row of wedge-shaped, partially confluent black spots. Forewing predominantly black, with white base to the costal margin, white cell-streak and antemarginal spots placed in pairs.

E. deione, an Indo-Malayan species, runs parallel with *alcathoë,* beginning in Sikkim, and spreading thence over Siam and Perak on to the Macromalayan islands and their satellites. Wings rounded, upper surface
deione. mostly with brilliant, but sometimes also with dull blue reflection. — **deione** *Wastw.* Forewing with the exception of a very narrow black marginal area with brilliant dark blue gloss, only the basal part of the hindwing with dull reflection. Hindwing above only rarely with the rounded submarginal spots of the under surface showing through. ♀ with one costal and three white discal dots, which in the ♂ are reproduced more weakly. Sikkim
arida. to Upper Burma. — **arida** *form. nov.*, only known to me from the Ruby Mines, Upper Burma, is a dry-season form, essentially smaller than Sikkim and Assam examples. Both sexes with small white dots on the upperside
limborgi. under surface entirely without spots except for the violet discal dots, which are also much reduced. — **limborgi** *Moore* is a local race with very large white, elongate-oval submarginal spots on both sides of the hindwing. On the other hand the white dots of the forewing are entirely absent in the ♂♂ and almost entirely in the ♀♀. I found the butterfly commonly on flowerings shrubs in Siam and South Annam. Other
menetriesi. localities: Tenasserim, Lower Burma, Mergui Archipelago. — **menetriesi** *Fldr.* (= pinwilli *Btlr.*) is a much darkened form, but the ♂ still with intensive blue reflection and hindwing with a double row of brown-grey
epiphaneia. submarginal spots. Malay Peninsula. — **epiphaneia** *subsp. nov.* approaches the preceding, but differs in having less of the blue reflection on the forewing and in the longer and mostly pure white submarginal strigae of the hindwing. West Sumatra. Examples from North-East Sumatra form a transition to *menetriesi.* According
kheili. to Martin common in the plains, preferring the flowers of a heliotrope-like shrub. — **kheili** Weym. is not only a much darkened race, but is also of smaller size than *epiphaneia.* Forewing with three white subapical dots on deep black ground with magnificient blue gloss. Hindwing ornamented with two rows of submarginal dots of equal size. Nias. — **seitzi** *Hag.* bears likewise only two small white subapical dots, but isessentially

larger than *kheili* and has a similiar arrangement of the two rows of white dots on the hindwing above and beneath. Mentawej Islands. — **pasina** *Fruhst.* differs from *seitzi* and *kheili* in having the blue reflection on the forewing scarcely perceptible, the sexual stripe longer and broader and both wings more copiously dotted with white. ♂: forewing with an admarginal row of white dots which start from the submedian and extend to the radials, becoming gradually smaller. Above them three larger pure white subapical dots complete the row. The hindwing bears two parallel submarginal series of white elongate spots of almost equal size. which are repeated also beneath. Under surface: white spots more distinct than above; on both wings a violet dot before the apex of the cell. Forewing further with another violet dot in the middle of the costal margin and three small violet circumcellular spots of unequal size, as well as some dots at the base. The long grey sexual spot always present in the allied forms between the third median and the submedian on the forewing beneath is absent in my example, perhaps only accidentally. For the rest the submedian is accompanied by two rows of stripes of scent-scales with a dull gloss, which are suddenly much widened basally. ♀: both sides with very slight blue reflection, ground-colour black-brown. Forewing with two rows of white submarginal spots, of which the proximal one is composed of larger, proximally pointed spots. Under surface: in the middle of the costal margin two whitish strigae, the lower transcellular spots elliptical, very large. Between the lower median and the submedian the usual long violet-grey streaks of *deione*. Hindwing with five median dots. Island of Pulo-Tello in the Batu Group. From Engano no *deione*-race is known. — **wallengreni** *Fldr.* (86a) is a highly specialized branch, almost worthy of specific rank, the general character of which is so different that Moore included it in the Moluccan "genus" *Betanga*. Only one of my 20 examples shows a dull blue reflection which recalls the continental race. Together with the form figured, with white subapical dots on the forewing, which are sometimes accompanied by 3—4 submarginal dots, there occur also others entirely without dots (**demaculata** *form. nov.*). The form with more or less obsolescent wedge-spots is very rare in both sexes. Distributed over the whole of Java, ascending to about 600 m., but in the west much scarcer than in the east. — **sapitana** *Fruhst.* Approaches *kheili* from Nias in habitus, but differs from all the known forms in the brown, sometimes even light brown and sharply defined distal border of both wings, through which whitish brown dots show through from the under surface. Hindwing similar to that of *epiphaneia* and *menetriesi,* i. e. with long, oval whitish submarginal wedge-spots. somewhat shaded with grey. Lombok. at elevations of 600—700 m; flies April—June; named from Sapita, a village situaded at the edge of the timber-forest. — **menodice** *subsp. nov.,* the most easterly form known, has almost entirely lost the blue reflection and the brown colour, rudimentary in *sapitana*, extends nearly to the middle of the wing, whilst at the same time the submarginal wedge-spots disappear on the upperside of the hindwing, only remaining beneath as in *seitzi* and *kheili.* Sumbawa. — **zonata** *Druce* is the subspecies inhabiting the whole of Borneo, which has been brought to Europe in large numbers; it shows above no trace of white dots and a dull deep blue reflection overspreads the entire forewing. Some examples are almost larger than continental specimens; the sexual stripe very long, broad. Hindwing beneath only with isolated short white interneural striae. — **masina** *Fruhst.* is founded on a smaller form or race from south-eastern Borneo with narrower forewing, very short, thin sexual stripe and a complete row of distinct submarginal striae. South-East Borneo, neighbourhood of Amuntai. ♀ of both the Borneo forms extraordinarily rare, apparently not yet described at all. — **transpectus** *Moore* is only known to me from a ♂ in the Museum at Stockholm; it differs from *epiphaneia* and *menetriesi* in the paler brown hindwing and bears only two or three insignificant submarginal wedge-spots and an antemarginal row of seven small dots on the hindwing above. Island of Billiton. — Finally, **cyllene** *Stgr.* is a race which shows a distinct retrogression to the continental type; both sexes with very long, narrow submarginal streaks on the hindwing, which are also prominent above; ♀ with one, sometimes even two rows of grey-dusted antemarginal dots on the forewing. Under surface as in *epiphaneia*, but with the white wedge-spots a little narrower. Palawan; flies in January.

pasina. *wallengreni.* *demaculata.* *sapitana.* *menodice.* *zonata.* *masina.* *transpectus.* *cyllene*

E. swainsoni inhabits exclusively the Philippine region, from whence it has advanced into northern Celebes, and it is only to be wondered at that no race of this species has yet been discovered in Sandakan. The separate branches of the collective species are so different that the question has been raised whether some of them should not be regarded as good species; but as in analagous cases the investigation of the genitalia yielded no result, we have abstained from exmaining them and for the sake of uniformity all the forms are here treated as geographical subspecies. — **swainsoni** *Godt.* differs from the figured *bazilana Fruhst.* (82a) in having the white subapical spots of the forewing, which form an almost quadrate area, more than twice as broad. The proximal row of submarginal spots is incomplete, only 2—5 dots being present in both sexes. Ground-colour similar to that of *suluana Moore* (84d), the under surface even paler, grey-brown. but with pure white areas and spots. Luzon; according to Semper not extending southwards beyond 14° Lat. — **butra** *Stgr.*, from Palawan, approximates to *swainsoni* in the under surface, which, although somewhat darker, almost exactly agrees in the weak development of the submarginal dots of the hindwing. *butra* has also the concave inner margin of the forewing in common with *swainsoni,* but differs considerably in the absence of the large white subapical area of the forewing, in place of which there is only a series of mostly strong white submarginal spots. But examples also occur with scarcely perceptible dots. — **dealbata** *form. nov.* Forewing at

swainsoni. *butra.* *dealbata.*

lucasi. the base dark brown, distally of a characteristic grey-brown shade. Palawan, not rare in January. — **lucasi** *Moore,* described from Mindanao, is one of the most easily caught butterflies of the island; SEMPER possessed over 450 examples. The white spots on the upper surface of both wings smaller, and hence more isolated. than in the Bazilan race. Ranges according to SEMPER over all the central and southern Philippine Islands.

bazilana. — **bazilana** *Fruhst.* (82 a), of essentially darker brown ground-colour, with purer white spots on both wings, of which especially the intramedian spots on the forewing are more pronounced than in *lucasi.* Bazilan.

suluana. February to March. — **suluana** *Moore* (84 d), with the general colouring light brown, bears more regular submarginal spots on the forewing and larger antemarginal dots on the hindwing. ♀ as a rule with more numerous

donovani. white discal dots. Sulu Archipelago. — **donovani** *Fldr.*, unknown to me, must be very rare, as it has not been brought to Europe again since FELDER's time. There is perhaps also a mistake as the locality on the

kuroiwae. part of the author. North Celebes. — **kuroiwae** *Mats.* is a race from the Loo Choo Islands, only discovered in 1905, which is strikingly similar to *lucasi.* Subapical spots of the forewing as in *bazilana,* but the submarginal band of the hindwing only composed of small rounded patches as in *butra.* Moreover, the subanal spots of the forewing much reduced. Inner margin of the forewing moderately concave, as in *swainsoni.* Described from the Yayeyama.

abjecta. **E. abjecta** *Btlr.* (82 c ♀ not ♂), a completely isolated species, ♂ with narrow forewing, strongly excurved at the inner margin. Sexual stripe long and broad as in *swainsoni,* ground-colour light brown with darker costal area on the hindwing above. Both wings beneath distally paller, with delicate violet tinge. Forewing with submedian streak, which as in *swainsoni* occurs only in the female, hindwing with 2 pairs of interneural stripes, which are longer and broader than above. Palau Islands.

E. diana is peculiar to the Celeban subregion, is divided into three local races on the main island

diana. itself and extends southwards on to the elongated satellite island of Saleyer. **diana** *Btlr.*, the name-type, is the race richest in colour and most widely distributed in collections. Forewing with whitish violet sexual stripe, two very large, nearly quadrate ultracellular patches, several costal and submarginal dots. Hindwing with two discal spots, a series of submarginal spots and in addition a row of marginal dots. In the ♀ there are further whitish discal patches beside and beyond the cell of both wings. Under surface grey-brown with grey or violet-white patch in the median area of the hindwing. Common on low-lying meadows with long grass in the coast-forests of Toli Toli, in November to December. Extending southwards to the Bay of Palos

horsfieldi (Donggala, August). Common everywhere in the Minahassa. — **horsfieldi** *Fldr.* is the strongly darkened race which inhabits the southern arm of Celebes and is at the waterfall of Maros one of the first butterflies which the traveller encounters. Sexual stripe of the ♂ black. Submarginal spots of the hindwing mostly larger and the whitish violet areas which in *diana* surround the spots on the forewing are wanting in the ♂♂,

fruhstorferi. whilst in the ♀♀ as a rule the upper transcellular patches are absent. — **fruhstorferi** *Röb.* is a rainy-season

tombugensis form, in which the white costal and cell-dots of the hindwing almost entirely disappear. — **tombugensis** *Fruhst.* (82 a) is the melanotic extreme of the species, as a rule without a trace of white discal patches and with grey-black sexual stripe on the forewing. ♂♂ from Tombugo are the darkest, while ♀♀ from the more southerly harbour of Kendari form a transition to *horsfieldi* in the white intramedian patches of the forewing.

laodikeia. — **laodikeia** *subsp. nov.* is a pronounced geographical form, whose discovery is due to Dr. MARTIN. Ground-colour deep black-brown, almost without a trace of a violet tinge; sexual stripe grey-black without any violet bordering; subapical and submarginal spots of the forewing extremely prominent, pure white, three times as broad as in *diana,* contrasting vividly with the dark ground-colour. Submarginal patch of the hindwing as in *horsfieldi,* cell- and median dots absent. Saleyer, in January.

E. maura replaces *diana* on the adjacent islands to the east and differs principally in its small size, length of the forewing 33—34 mm. against 40—43. Above and beneath unicolorous brown, only with white

maura. discal spots without violet tinge, sexual stripe always black-brown. — **maura** *Hoffr.* similar to *corvina Fruhst.*

corvina. (86 a), but without white cell-spot and without any dots on the hindwing above. Described by HOPFFER from Celebes, but really coming from the Togean Islands in the Tomini Gulf. — **corvina** *Fruhst.* (86 a) bears above as a rule only one fine white dot before the apex of the cell and 2 small obsolescent spots between the median veins of the forewing, 3 submarginal dots and a white cell-spot on the hindwing. All the spots are enlarged on the under surface and their colour is changed to violet. The submarginal row is more complete

wiskotti. and on the hindwing there are further 3—4 minute discal dots. Sula Mangoli, Sula Besi. — **wiskotti** *Röb.* has the same arrangement of all the white spots and beneath of all the violet ones, except that they are all, in particular the cell-patch of the hindwing, about three times larger than in *corvina.* Bangkai.

lewa. **E. lewa** *Doh.* (85 a) is the darkest extreme of a series of forms which inhabit the eastern Micro-

baudiniana. layan islands, of which **baudiniana** Godt. (= orope *Bdv.*) must be regarded as the name-type. From *baudiniana,* which is unicolorous brown, *lewa* differs in the deep violet or steel-blue sheen of the upper surface of the forewing and the absence of the series of white dots on the hindwing. On the underside of the hindwing a yellowish grey discal area is noticeable, in which are placed 5—6 whitish yellow patches in an irregular row. Cells of both wings with violet spot, which is distally surrounded by 5—6 dots of the same colour

Sumba; occurring in abundance. — As **E. orope** Boisduval has first figured a form which approaches *fabricia* (86 a), of which, however, *baudiniana Godt.* is pretty certainly the oldest name. Godart apparently described a ♀, as he does not mention the scent-stripe, whilst Boisduval's figure is an excellent and unmistakable representation of a ♂. But whereas Godart quite correctly names Timor as habitat, Boisduval erroneously gives Polynesia as the locality of his type. *orope Bdv.* differs from *fabricia* in having the white bands somewhat broader and hence somewhat more continuous on the forewing. Dots of the under surface as in *lewa,* but the hindwing grey-white from the cell onwards. Timor. taken by Doherty in May. — **belinda** *Btlr.* is the polymorphic race from Wetter, erroneously described by Butler as from Sumatra, which apparently produces 3 different seasonal forms. The name-type seems to belong to the rainy season; it is very similar to *lewa* from Sumba, but smaller, without appreciable blue reflection, but with the white subapical area of the forewing almost as large again. Hindwing either without or only with a few distinct submarginal dots and very small antemarginal ones. Forewing in both sexes with only one white spot between the upper and lower median veins. On the under surface, however, in contrast to *lewa* the submarginal white markings occur as relatively large wedge-spots. The violet discal patches prominent. **oropina** *Röb.* is an intermediate form, in which on the hindwing the submarginal row of wedge-spots is present above also and is accompanied by distinct antemarginal dots. Flies in May. Finally, **latistriga** *form. nov.* is probably the product of an extreme dry season and forms a connecting-link with *baudiniana* and *fabricia* in the essentially broadened intramedian spots of the forewing and in the widened, band-like submarginal spots of the hindwing, which as in *fabricia* are confluent with the marginal dots. Flies perhaps in July and August. — **fabricia** *subsp. nov.* (86 a) differs from *baudiniana* chiefly in having the white submarginal bands of both wings narrower and more sharply defined. A ♀ belongs to the form *oropina Röb.* Letti, Kisser, apparently not rare. — **domitia** *subsp. nov.* (84 d) is the largest race known and with correspondingly widened macular bands, of which that of the hindwing in the ♂ is composed more of rounded instead of elongate patches and is not confluent with the marginal dots. Under surface of both wings paler and more uniform grey than in *fabricia.* Roma; discovered by H. Kühn.

orope. *belinda.* *oropina.* *latistriga.* *fabricia.* *domitia.*

E. eleutho is the oldest name of an Australian-Pacific species of black-brown ground-colour with large quadrate postdiscal spots on the forewing and a white submarginal band on the hindwing which varies in breadth according to the race. From Australia *eleutho* has spread to Guam and the Ellice and Samoa Islands and has advanced westward over the Timor-Laut Group to Babber and Dammer, occurring on those islands which have not been reached by *baudiniana*; only on Kisser both are found. The variability of the collective species has led Moore to divide the separate island forms among three of his genera. — **sacerdos** *Btlr.* (84 d), described from Larat in the Tenimber Group, bears very broad white spots and bands, as a rule much more extended than in the example figured. Under surface of the forewing black, that of the hindwing pale brown, in each cell a larger violet punctiform spot and a transcellular row of 3—7 violet patches, partly streak-like, the forewing in addition with 2 small costal spots. Base of the hindwing with 4—5 white dots and both wings also ornamented with white marginal dots placed in pairs. The pattern of the upper surface is reproduced beneath. Sometimes there is a second thin scent-stripe between the glossy, silky, deep black sexual stripes. Timor-Laut, Aru, Key. — **eleutheria** *subsp. nov.* (84 d) is a specially large race, with extended quadrate white spots on the forewing, particularly in the ♀. Beneath with brilliant light blue cell- and discal patches. Island of Teeon. — **ancile** *subsp. nov.* (82 d) is characterized by the narrower white markings of both wings, the intermedian spots of the forewing not quadrate, but mostly elongate-oval. Dammer, Babber. Kisser, very common. — **corinna** *McLeay* (= lewisi, angasi *Fldr.,* boisduvali *Luc.?*) has all the white spots and bands slightly tinged with yellowish, somewhat smaller than in *eleutheria,* and hence apparently more proximal, distally more deeply incised than in *sacerdos* and *ancile.* Australia, from Sydney to Cape York. — **euclus** *Misk.*, which Waterhouse places as a synonym in the Catalogue of Australian Lepidoptera, appears from its author's description to be an interesting aberration of *corinna,* characterized by the absence of the antemarginal white spots on both wings and the much reduced white bands of the hindwing. Cape York. — **eleutho** *Quoy,* the name-typical form, with somewhat shorter wings and very large quadrate spots on the forewing Under surface a peculiar light grey, earth-coloured, the spots on the discocellular relatively large, but the violet or blue discal patches almost entirely suppressed. Island of Guam in the Ladrones, according to Moore also from Samoa and the Ellice Islands in the British Museum. — **proserpina** *Btlr.* is a conspicuous local form with delicate markings on the wings and considerably reduced white patches, which are occasionally slightly tinged with violet. Marginal dots of the hindwing in the ♂♂ mostly absent; the submarginal patches reduced to small wedge-shaped or rounded punctiform spots. The small circumcellular dots on the underside of the hindwing are, however, distinct, in contrast to *eleutho.* Viti-Levu, apparently occurring in abundance.

sacerdos. *eleutheria.* *ancile.* *corinna.* *euclus.* *eleutho.* *proserpina*

E. schmeltzi *H.-Schäff.* is a species rare in collections, known from the Samoa Islands: type a ♀, whose forewing bears 3 costal and 4 large white subapical patches; in addition there is a white spot in each cellule between the radials and the upper median veins. Upper surface of the hindwing with three larger proximal rows of submarginal dots and three smaller distal rows, only extending to the first median vein. Under surface with a white spot before the cell and somewhat more complete reproduction of the white markings of the upperside.

schmeltzi.

whitmei. **E. whitmei** *Btlr.*, with the forewing 30 mm in length, one of the prettiest of the brown Euploeas and a true Oceanic butterfly in its small size. Locality: Lifu in the Loyalty Islands, to the east of New Caledonia. Ground-colour dark chocolate-brown with the marginal area slightly lighter, especially on the hindwing. Forewing with very short, but broad sexual stripe and two small subapical dots. Hindwing with a distal row of small, somewhat irregularly placed marginal dots and a submarginal row of 3—4 somewhat larger spots. Underside with a more complete double row of white dots, to which is further added a discal group of 7 circumcellular spots and a cell-spot. Forewing likewise with a violet patch before the apex of the cell, *childreni.* two transcellular and two white intramedian patches. — **childreni** *Moore,* described from an example in coll. Oberthür from "Java", is perhaps synonymous with *whitmei* or a local race of it from the Pacific region. All that is certain is that *childreni* does not occur on Java.

E. guerini, hitherto only known from New Guinea and the Aru Islands, was recently discovered in Australia also. Apparently constant on the Aru islands, on the main island of New Guinea it is one of the most variable species, so that no less than 10 specific names have been given to the local race of British New *punicea.* Guinea, which, however, for the most part do not represent aberrations worth naming. — **punicea** *Gr.-Sm.* (84 c) is the oldest name, which was given to the race from Dutch New Guinea and according to the material I have examined from Humboldt Bay the form from Kaiser-Wilhelmsland is identical with it. On the figure the delicate, plum-blue tinge and the somewhat lighter marginal area are unfortunately not brought out well. The under surface is cocoa-brown, occasionally with dull, light violet reflection on the distal parts. Both wings with light blue cell-spot and two resp. five discal dots. Forewing in the ♀ further with the submedian streak found in most Euploeids, in place of which in the ♂ the glossy brown sexual stripe shows through from above. In the form *punicea* the white subapical patches of the upperside are also reproduced beneath. — *bruno.* **bruno** *Sm.,* under which name the New Guinea *guerini* in general pass in the trade, designates a slight variation, *palilia.* in which the forewing shows in addition a complete submarginal row of white spots. — **palilia** *form. nov.* (84 e) has no white spots on the forewing, but in their place a light violet tinge, which extends as a band *amethysta.* to the middle of the wing. — In **amethysta** *form. nov.* (82 e) both wings are adorned with a broad violet marginal area and the discal area of the hindwing beneath is whitish. This form sometimes also occurs in *progressiva.* combination with the spotted typical form *punicea.* — **progressiva** *form. nov.* (84 c) are examples with plum-blue upper surface, without white splashes and without violet margin, but distally more or less tinged with *violetta.* light brown. Here belong 36 out of 72 pairs, thus exactly half the examples in my collection. — **violetta** *Btlr.* (81 b) is the oldest name for the local race from British New Guinea, erected from examples from Port Moresby. According to the series of 12 pairs from Milne Bay before me the local form is very constant; all the examples bear much larger white subapical spots than *punicea*, which are either covered or bordered with blue or violet, more or less densely sprinkled scales. Submarginal band of the forewing nearly always complete. On the upperside of the hindwing there are 1 or 2 submarginal intramedian spots. *pleiadis Btlr.* *ordinata.* and *dolosa Btlr.* sink to *violetta* without further discussion, as based on smaller individuals. — **ordinata** *Moore* *denticulata.* is a form with a complete row of submarginal spots on the forewing. — In **denticulata** *Moore* these are strongly *bipunctata.* reduced. — **bipunctata** *Moore* refers to the ♀♀ already mentioned with two submarginal spots on the hindwing *astraea.* above. — **astraea** *Moore* has the spots essentially widened and for *stella, siderea, louisa Moore* I can give no distinctions at all. But from Moore's descriptions it is tolerably certain that neither the form *palilia, amethysta* nor *progressiva Fruhst.* has as yet been observed in British New Guinea: it is also interesting to notice that the pairs received by me from the eastern parts of Kaiser-Wilhelmsland all incline to the form *punicea* and consequently form a distinct transition to *violetta,* whilst *progressiva* and the violet-banded individual aberrations predominate especially in Astrolabe Bay, near Friedrich-Wilhelmshafen. It is not impossible that *tenebrosa Sm.* *tenebrosa.* and *lachrimosa Sm.*, which, however, its author expressly compares with *netscheri*, belong to *guerini.* — **tenebrosa** then about corresponds to *progressiva* and would have to stand as the name-type in place of *punicea*, and *lachrymosa.* **lachrymosa** *Sm.* would be the race from the island of Jobi, according to Smith without blue reflection and *amycus.* beneath somewhat paler than *tenebrosa.* — **amycus** *Misk.*, which Waterhouse cites in the Catalogue of Australian Lepidoptera as a separate species, is judging from the description a *guerini*-race. ♂ above dark velvety brown, with lighter distal margin. Apical band composed of 4 irregularly shaped, slightly clouded white spots, of which the upper two are the smallest. A small round white spot is placed between the median veins near the distal margin. Hindwing dark brown with lighter marginal area and two small white submarginal spots near the apex, of which the lowest is nearly obsolete. Under surface velvety brown with a violet spot before the end of the cell, 5—6 beyond the cell and five white larger subapical patches. Locality Cape York. — *guerini.* **guerini** *Fldr.*, the first named branch-race of the species, apparently inhabits exclusively the Aru Islands; it has not yet been observed on Key. Habitus larger than in *punicea*, forewing somewhat longer and always with a complete row of submarginal spots, which in the ♀ are continued also on the upperside of the hindwing. — *enna.* **enna** *subsp. nov.* is before me from Salawatti; upper surface deep black, with slight dark steel-blue gloss and forewing with a complete row of almost uniform pure white spots, of which the upper three are wedge-shaped and the third is distally slightly incised. Under surface with very large, light blue cell- and ultracellular spots, deep black with dull blue tinge.

E. illudens *Btlr.*, a small species, has about the same colouring as *cerberus Btlr.* (81 c), but the wing-contour much as in *corvina Fruhst.* (86 a); it is so far only known from the Bismarck Achipelago. in my collection from New Lauenburg and New Pomerania; according to Butler also occurring on New Mecklenburg, from whence, however, I have before me a much larger race. The ground-colour of *illudens* is dark brown, forewing of the ♂♂ with three to four, that of the ♀♀ with five small grey-white subapical dots, underside with light blue cell-spot and three resp. six circumcellular patches. Forewing with a row, hindwing with a half row of small antemarginal spots. — **lygdamis** *susp. nov.* is a larger form from New Mecklenburg, with purer white and more prominent spots on the upperside and larger and lighter blue ones on the underside of both wings. *illudens.* *lygdamis.*

E. decipiens *Btlr.* is a species nearly allied to *illudens* with the sexual stripe much longer, broader and distally not ovally prolonged. Apex of the forewing more pointed, hindwing with only two short rows of antemarginal dots. Described from New Lauenburg. in my collection from Herbertshöhe. *decipiens.*

E. hemera *spec. nov.* (86 a), similar to *cerberus Btlr.*, with the wings of the same shape; inner margin of the forewing strongly convex; ♂ above dark brown, ♀ somewhat lighter. ♂ above without, ♀ with a few unimportant small submarginal spots. Sexual stripe of the ♂♂ narrow, short, in some examples nearly suppressed; dots on the under surface as in *illudens*. Island of Mafor or Mefor in Geelvink Bay. — **nesis** *subsp. nov.* is a darker and much smaller race, which differs from *hemera* beneath in having a more complete row of violet submarginal dots. Dammer. *hemera.* *nesis.*

E. irene *spec. nov.* (86 c), with more rounded wings, of larger size than the preceding (usually about equal to *anthracina Btlr.* from Amboina), has like *anthracina* and *deione Westw.* a very long broad sexual stripe on the forewing. Ground-colour dark coffee-brown, ♀ little lighter, both sexes wihout a trace of dots on the upperside. Under surface light coffee-brown with a broad yellowish patch in the median part of the hindwing, such as occurs also in *deheeri Doh.* and *radica Fruhst.* Forewing with two, hindwing with five transcellular patches surrounding the cell-spot. Forewing in the ♂ with a violet stripe between the median veins, distally curved somewhat downwards, ♀ with the customary submedian streak. Fergusson and Kiriwina. *irene.*

E. vitella *Montr.* and **transfixa** *Montr.*, from Woodlark Island, possibly approximate to *irene*, but I have never seen these forms.

E. melanopa, an exclusively Papuan species, is distributed in collections under the newer name *netscheri Snell.* — **melanopa** *Röb.*, described from Sekar, on the southern arm of West Dutch New Guinea, is the darkest branch-race known. Upper surface without markings, forewing dark coffee-brown with the margins but little lighter, hindwing only dark brown basally and in the cell, distally yellowish brown. Under surface lighter, somewhat tan-coloured. Dots of the underside as in *irene.* Doherty took the form at Kapaur, Kühn also in Etna Bay. In the Kayu-Meru Bay examples occur with large white subapical patches on the under surface, which are present on the forewing as small spots shaded with grey-brown (= **albifrons** *form. nov.*, 86 b). Together with it occur in the same district ♂♂ with white patch on the hindwing above and the entire anal third of the hindwing beneath tinged with grey-white (= **delicia** *form. nov.*, 86 b). — At the Humboldt Bay and especially at Dorey in Geelvink Bay on the northern coast of Dutch New Guinea occurs **netscheri** *Snell.*, with the upper surface uniform light brown, of which a good figure was given in the Tijdschrift voor Entomologie 1889. – **julica** *subsp. nov.* (86 b) has a rather monotonous upper surface, the distal margin only in the ♀♀ appreciably lighter, but the under surface is always more or less inclined to the *delicia*-pattern. Waigeu, Salawatti. — Finally, **parca** *subsp. nov.* inhabits German New-Guinea, but is very rare. Distal margin of the underside of both wings reddish brown, the upper surface darker than in the forms already mentioned. According to Hagen *parca* occurs from December to April at the Astrolabe Bay. — **cissia** *subsp. nov.* is before me from Misol; above and beneath characterized by a light grey-brown, sharply defined margin on both wings and with large violet-white discal patches on the under surface; the ♀♀ bear subapical patches on the underside. thus somewhat resembling *albifrons*. Flies in January. *melanopa.* *albifrons.* *delicia.* *netscheri.* *julica.* *parca.* *cissia.*

With **E. duponcheli** begins a small group of species which is distributed from the Moluccas to the Solomons and is distinguished by a long, broad silky stripe on the forewing, which particularly in the eastern species reaches the maximum of development among all the Euploeids. The separate races and species are all to be met with in great abundance in woods at the sea-coast. — **anthracina** *Btlr.* Habitus about as in *deione Westw.* Ground-colour black-brown with the margins slightly lighter; ♀ above nearly always with indistinct grey-white submarginal spots (Amboina) or these distinctly shining through on both wings (Ceram). The species is often confused with *climena,* but the intramedian patches of the forewing and the submarginal dots of the hindwing are all more pronounced. Amboina, Saparoea. — **lykoatis** *subsp. nov.* has the ground-colour lighter brown throughout than *anthracina*, the forewing of the ♀♀, but especially the hindwing, has the white dots better developed, and the submarginal patches of the under surface are likewise more prominent than in Amboina examples. East Ceram, very common. — **duponcheli** *Bdr.* on the other hand is a considerably darkened race; ♀ smaller than in *anthracina* and without a trace of transparent submarginal dots. *anthracina.* *lykoatis.* *duponcheli.*

Under surface more delicately dotted with blue throughout, the rows of dots on the hindwing not continued
odingdensis. to the anal angle even in the ♀. Buru. — **dodingensis** *Moore* is characterized by the strikingly broad sexual stripe of the forewing in the ♂♂ and the uniform dark brown colouring of the upper surface. Dots on the
varina. underside even more reduced than in *duponcheli*. North Moluccas: Halmaheira, Batjan. — As ab. **varina** *form. nov.* we indroduce an interesting aberration with a row of light brown submarginal patches on the forewing above, which beneath are magnificently blue-white. The hindwing bearse long whitish violet intramedian
moluccana. streaks. Both wings distally tinged with steel-blue. Batjan. — **moluccana** *Swinh.* is the darkest of the Moluccan races, altogether smaller than *dodingensis*, ♀ above sometimes with two or three small median dots. Dots of the under surface very delicate, similar to those of *dodingensis*. No representatives of *duponcheli* are yet known from New Guinea, but two species occur commonly on the Solomons.

fraudulenta. **E. fraudulenta** *Btlr.* ♂ somewhat larger than *anthracina,* with dark brown androconia-spot, filling up the whole cell, and light brown anal margin on the hindwing. ♀ above dark brown, with darker marginal area, a rather large white cell-spot and two transcellular spots. ♂ with the sexual stripe on the hindwing very long, yet only a third broader than in *anthracina*. The under surface of the forewing is characterized by a long, concave, somewhat sausage-shaped whitish violet spot, bent downwards at the sides, placed between the middle and lower median veins before the grey cell-stripe which shines through from beneath. In the ♀ there is further an unusually long band, extending to the base, likewise whitish violet, which occupies the inner margin of the forewing behind the submedian. Under surface of the hindwing as in *anthracina,* but with two rows of very large antemarginal dots. Widely distributed on the Solomon Islands: Shortlands, Bougainville, Choiseul, Ysabel and Rubiana. On Renonga Ribbe captured a specimen with whitish sheen on
lystra. the upperside of the hindwing. — **lystra** *subsp. nov.* Habitually smaller than *fraudulenta*, with reduced white discal dots on the forewing and more uniformly light brown hindwing. Underside of the forewing in addition to the usual cell-spot and 2 transcellular patches with a row of 3 thin striae before the apex of the cell, which are wanting in the other *fraudulenta*-forms. Treasury Island.

nechos. Finally, **E. nechos** *Math.,* with more rounded wings than the preceding, has the sexual bands of the forewing nearly 1 cm. in breadth. Ground-colour somewhat lighter brown, the characteristic intramedian stripe on the underside of the forewing shorter than in *fraudulenta,* distally deeply incised, proximally not excurved posteriorly. Antemarginal patches of the hindwing mostly absent. Ribbe met with the species up to many thousands on the small Solomon Island Munia, whole swarms were frightened up when anyone passed through the thickets; and in some places, where the natives had cut down wood, whole crowds of Euploeids were resting on the flower-covered stumps. Even in the dense forests there was not a twig and scarcely a leaf of the lower bushes on which a *nechos* was not settled. Ribbe learned from the natives that such swarms occur periodically, about every 10 years. Shortlands Islands, Bougainville.

megaera. **E. megaera** *Btlr.* is only known to me from the description. Ground-colour dark brown, the hindmargin lighter. Five subapical spots are placed in an oblique row. ♀ with a cell- and a costal dot and a row of small indistinct submarginal spots. ♂ with three subapical dots on the paler hindwing, ♀ with two rows of subapical dots. Under surface lighter brown than upper; ♂ with 7 antemarginal dots. Aru Islands.

E. morosa (= dalmani *Fldr.*) is an interesting species, and is the easiest to determine of all the *Crastia*. The sexual spot inserted between the middle and lower median vein is placed quite near to the
morosina. distal margin of the forewing and moreover is almost rounded instead of elongate and stripe-like. — **morosina** *subsp. nov.* (82 d). Above deep velvety black, hindwing with whitish grey costal margin and quite narrow black androconia-patch. Under surface with a violet cell-dot, two discal dots and an elongate, distally pointed intramedian stripe, which is placed exactly over the oval scent-spot. Hindwing besides the cell-spot with 5
morosa. violet discal and 3 subapical dots. ♀ somewhat lighter brown, above without a trace of dots. Obi. — **morosa** *Btlr.,* described from Halmaheira, not rare also on Batjan, is somewhat larger than the preceding; scent-spot elongate and larger. Under surface with more delicate discal dots than in *morosina.*

E. pierreti, described from Dorey (Dutch New Guinea), has the sexual spot likewise very near the distal margin of the forewing. It varies in length in the separate local races, but in all the forms is somewhat
numantia. curved down distally. — **numantia** *subsp. nov.* (86 b) shows a shorter sexual patch, which in some ♂♂ is somewhat narrower, but in others broader than on the figure, where unfortunately it could not be brought out very distinctly. Under surface of both wings basally dark coffee-brown, the distal margin of the hindwing shaded with whitish yellow. Forewing with a cell-dot and 2 or 3 discal dots, hindwing with a cell- and 5
pierreti. discal dots. Not rare; Waigeu. — **pierreti** *Fldr.* is above somewhat lighter brown throughout than *numantia*,

the scent-spot long, large, distal margin of the hindwing, particularly that of the ♀, rather dark tan-coloured. Discal dots on the under surface very weak. Marginal area of the hindwing in the ♀♀ almost whitish. Dutch New Guinea. — **erana** *subsp. nov.* may be recognized by having the silky stripe on the forewing nearly twice as long as in *numantia* and the upper surface of both wings very dark, with the yellow-brown distal margin standing out rather sharply. Under surface dark coffee-brown, with bone-yellow marginal area extending to the cell and extremely prominent whitish violet discal patches. German New Guinea. *erana.*

E. lugubris *Sm.*, described from the island of Biak, has the sexual stripe as short as in *morosa Btlr.* Hindwing as pale brown-yellow as in *numantia Fruhst.*, the size larger than in *morosa* and *numantia*, but the hindwing more similar to that of *morosa*, i. e. with anteterminal dots, which are absent in the *pierreti*-series. — **fuscosa** *Sm.* is a local form of the preceding, above and beneath darker brown, but hindwing with the white dots more indistinct. Mysore, collected at the harbour of Korrido. Only 2 pairs known. *lugubris.* *fuscosa.*

E. lapeyrousei *Bdv.* is a species probably allied to *pierreti*, said by Moore to occur on Buru, but by Oberthür, who possesses the type, in Dutch New Guinea. According to Oberthür Boisduval's description is much too brief for it to be possible to judge of the species from it. Moore states that the sexual spot is much narrower but longer than in *pierreti* and the under surface more prominently spotted. *lapeyrousei.*

E. torvina *Btlr.* An extremely elegant species with very narrow wings and a large sexual stripe, distally and posteriorly rounded. Forewing deep velvety brown with narrow distal area, somewhat lighter brown but tinged with violet. Hindwing with somewhat broader yellow-brown anal margin, under surface light chocolate-brown, hindwing with very narrow, sharply defined pale brown marginal area and prominent, rather large white-yellow antemarginal dots. Disc and cell as in *morosa*, but more delicately dotted. New Hebrides: Aneitum; Lifu; rare in collections. *torvina.*

E. paykullei *Btlr.* is a nearly allied, but distinct species, with even more delicate colouring than the preceding. Subapical region of the forewing and marginal area of the hindwing narrowly lighter, band-like, light brown instead of blackish, like the rest of the upper surface of both wings. Underside of the forewing also margined with lighter brown, hindwing without the antemarginal dots. Vate, Aneitum and Mota in the New Hebrides. *paykullei.*

E. brenchleyi *Btlr.* is wanting in my collection; it nearly approaches *paykullei*, from which it differs chiefly in having the hindwing almost entirely margined with white, recalling *eurypon Hew.* (86 c). Solomon Islands, without more exact locality, and discovered on a cruise to various Polynesian islands. *brenchleyi.*

E. eurianassa, one of the most beautiful species of *Euploea* known, exclusively inhabits the Papuan region and is a faithful copy of *resarta Btlr.* (82 b), from which it is at once distinguishable by the very long scent-patch of the forewing. — **cumaxa** *subsp. nov.*, from Kaiser-Wilhelmsland, is somewhat darker above, with narrower bands, partially suffused with yellowish, especially on the forewing. Like *resarta*, *cumaxa* does not occur further west than Finschhafen and hence is absent already from Astrolabe Bay. Hagen already knew the species in 1897 as very rare at Simbang, taken in December. — **terentilia** *subsp. nov.* (82 b) is a larger race than *cumaxa*, with the bands still more darkened; that of the forewing is sometimes entirely scaled with brown-grey and in parts nearly obsolete. The narrowing of the whitish submarginal band is even more noticeable beneath than above, in consequence of which the light brown anal margin of the hindwing is widened. Fergusson Islands. — **eurianassa** *Hew.*, described from New Guinea, probably coming from the British part of the island, is the most copiously white-banded local race and bears beneath the most delicate cell-dot and 5 discal dots of all the forms. Milne Bay, December, January; apparently not rare. *cumaxa.* *terentilia.* *eurianassa.*

Group Stictoploea *Btlr.* (1878)

(*Narmada Moore* 1880, *Doricha Moore* 1883.)

Larva as far as known with 3 pairs of tentacles, otherwise scarcely differing from that of the preceding group, but the appendages on the 3rd and 4th segments are considerably longer. Pupa as in *Crastia core.* Forewing with 2 sexual stripes. Neuration as in *Crastia.* Valve, as far as examined, similar to that of *Salpinx*, but much narrower, with elongate point, only moderately bent upwards.

E. coreta *Godt.*, of the same shape as *E. core Cr.*, but with somewhat smaller yellowish white submarginal patches on the forewing and shorter yellowish white wedge-spots on the hindwing. Forewing beneath with two white dots at the discocellular, which are absent in *core.* The species is very common in Southern *coreta*

India and is better known under the name *coreoides Moore.* Probably *consimilis Fldr.*, described as from Java, where it does not occur, is also a synonym of *coreta.* Larva with black head and white labrum, body of indefinite colouring, ground-colour blackish with blue dorsal line, some segments with yellowish, others with greenish violet sheen. Tentacles indigo-coloured, legs black. Pupa silvery with broad brown bands. Larva
montana. on the underside of young leaves of Ichnocarpus frutescens, much infested with ichneumons. — **montana** *Fldr.* is the Ceylon race of the preceding, with melanotic colouring of the forewing, on which above the submarginal dots are almost obsolete in the ♂♂ and much darkened in the ♀♀. Also beneath all the white markings are reduced. At certain seasons not rare, *montana* ascends from the plains up to about 2000 m. and is met with at Nuwara Eliya in May; sometimes it accompanies the common *asela* in its migrations.

E. harrisi, a continental Indian species with the most wonderful blue reflection, is broken up into two geographical races, and on account of itstendency to individual variability a whole series of names has been given to single, sometimes very unimportant forms. In spite of its commonness the early stages are still
hopei. unknown. — **hopei** *Fldr.* resembles the figured *binotata* (82 a), except that the hindwing bears a row of large white submarginal spots. This is the most northerly branch of the collective species, from Assam, Sikkim
binotata. and Cachar, described by Felder. — **binotata** *Btlr.* (82 a) is the type-form, hindwing without white wedge-spots, very common in Sikkim and Assam. Some examples have light blue, white-dotted subapical patches on the forewing, moreover the blue discal spots vary considerably in size; sometimes the two rows on the
pygmaca. forewing are prolonged and joined together. The cell-dot is sometimes suppressed. — **pygmaea** *Moore* is founded on a ♀ of the dry-season form, with violet upper surface and an elongate white wedge-spot in the
microsticta. cell of the forewing. — **microsticta** *Btlr.*, without exact locality, is probably a ♂-form of the rainy season,
regina. with extraordinarily large wings, and ab. **regina** *Moore* is an aberration without white submarginal dots
harrisi. on the hindwing and bearing very small white punctiform spots, described from Cachar. — **harrisi** *Fldr.* extends from Tenasserim to the Malay Peninsula, was described by Felder from Cochinchina, and collected by me in numbers in January in Siam, in February in a very small dry-season form in South Annam, and
crowleyi. in June and July in Tonkin. ab. **crowleyi** *Moore* is a melanotic aberration from Tenasserim, in which the
depunctata. two rows of white spots on the hindwing are absent. — **depunctata** *form. nov.* are specimens without whitish
discalis. submarginal dots on the forewing, which I have before me from Siam, and ab. **discalis** *form. nov.* is a rare aberration, with distinct blue cell- and 5 transcellular patches on the forewing, with normal hindwing, which bears a double row of white dots, and hence forms a transition to *hopei Fldr.* from Assam.

E. lacordairei is the name-type of a series of geographical races distributed over all the Macromalayan and some of the Micromalayan islands, which forms a very natural transition from *harrisi Fldr.* from the Indian continent to *dufresne Godt.* from the Philippines. Whether all the three species now regarded as separate belong to one collective species is a question which can only be solved by further anatomical research. As in certain species of *Salpinx*, so also here reliable conclusions as to the specific rank of individual forms
mithrenes. can scarcely be drawn at present from the only slightly different shape of the valves. — **mithrenes** *subsp. nov.*, from Sumatra, differs from the figured *harrisi* (84 b) in the darker, more steel- than light blue reflection on the upper surface and in the unequal and darker blue-violet submarginal spots of the forewing. Hindwing nearly always without submarginal rows of white spots, which are only absent on the under surface. On the other hand there is always an admarginal row of white dots on the hindwing and the discal spots on the underside of the forewing are very distinct. *pirina* is nowhere common and does not extend beyond the
convallaria. alluvial plains and the adjoining spurs of the mountains. ♀♀ are very rare. — **convallaria** *Thieme* is a well marked race with a row of very large, pure white subapical spots on the forewing, which are only at their proximal margin sprinkled with brownish atoms. Hindwing with five or six small white submarginal spots, which become smaller posteriorly. Upper surface deep brown, the violet gloss of the forewing is scarcely recognizable, and only in certain lights. Distal margin of both wings with the exception of the apical part with minute dots, which are placed nearer to the margin than in *lacordairei* from Java. Nias, only 1 ♂
nica. known. — **nica** *Fruhst.* differs both from *convallaria* and *pirina* in the particularly bright blue gloss even of the hindwing, in which it strongly recalls *harrisi*, except that the reflection is appreciably darker than even in Siam examples. Forewing with five very large, light blue submarginal spots without white centres; hindwing in the ♂ with three obsolescent, in the ♀ with pronounced, small subapical spots. Under surface deep black-brown with large whitish blue discal patches on the forewing. Hindwing, however, only with a few and
tyrianthina. nearly obsolete blue cell- and marginal dots. Engano, very rare. Flies in April. — **tyrianthina** *Moore*, described from North Borneo, in my collection also from South-East Borneo, closely approaches *mithrenes* from Sumatra, but is generally larger, the subapical blue spots of the forewing correspondingly larger, the blue gloss somewhat brighter on the forewing, but less bright on the hindwing and the under surface deeper
dotata. brown with the white marginal dots reduced — **dotata** *Fruhst.*, from Palawan, forms the transition to *dufresne Godt.* from the Philippines, has a more intensively blue gloss than *tyrianthina* and always bears, particularly in the ♀, large, rounded, light violet submarginal patches on the forewing, which traverse the entire wing to

the submedian. But the dots on the under surface are as insignificant as in the Borneo race Flies in January. — Whilst the races hitherto dealt with all show a more or less similar stamp, with **lacordairei** *Moore* begins *lacordairei.* a series of extremely variable geographical forms, probably due to the contrast of the seasons both on Java and on the more easterly islands. *lacordairei* inhabits the whole of Java, ascending from the sea-coast up to about 6—700 m. Examples from West Java, especially those from the Bay of Palabuan, taken by me in January in the middle of the rainy season, show in general only minute blue submarginal spots on the forewing and three subapical larger white spots on the hindwing (**defigurata** *form. nov.*) In East Java both sexes *defigurata.* commonly occur with very large, wedge-shaped, almost entirely white subapical spots on the forewing, which recall the ♀ of *Salpinx leucostictis* and may be designated **magniplaga** *form. nov.* ♀♀ from the Tengger Mountains *magniplaga.* of East Java bear wedge-shaped instead of rounded submarginal spots and an intramedian dot on the forewing beyond the cell and to some extent recall *E. eleusina*-♀. Finally, **decorata** *form. nov.* appears to belong to the *decorata.* most extreme dry season, with very large, white-dotted, light violet patches on the forewing and two complete rows of small white dots and small rounded spots on the hindwing above and beneath. — **baweanica** *subsp.* *baweanica.* *nov.* is as a rule larger than Javan examples, the submarginal patches of the forewing always larger, in the rainy-season form powdered with light blue. Under surface most resembling that of *tyrianthina Moore* from Borneo, deeper brown, with less dots. The dry-season form recalls *decorata*, but is still more pronouncedly dry-season, the hindwing bears even above two rows of light violet dots, and the ♀ bears in addition to these discal patches a blue splash before the discocellular, so that the resemblance to *eleusina* is still more complete (**eleusinida** *form. nov.*). Bawean, July-September. — **cassia** *subsp. nov.* differs from *lacordairei* in *eleusinida. cassia.* the smaller size, the more rounded wings, and the reduction of the blue reflection Under surface of the ♂♂ with pronounced dark blue discal patches, but almost without antemarginal dots. ♀ mostly with regular, distinctly wedge-shaped submarginal patches and almost without exception belonging to the form *eleusinida.* Coast-forests of Lombok, by preference sailing up and down at the edge of the woods on very hot days. — **tambora** *subsp. nov.* is a larger form, as a rule with almost whitish submarginal spots, which are continued *tambora.* on the hindwing. The under surface varies in two directions: the majority of the ♂♂ have the discal dots but little developed and no marginal ones, whilst a limited number show increased violet and white markings. Sumbawa. — **invitabilis** *subsp. nov.* is the maximum in the development of large, white-centred, light violet *invitabilis.* subapical spots on the forewing. The ♀♀ have large triangular spots, which pattern is accompanied by the *eleusinida*-markings. Disc of the wings on the under surface copiously decorated with violet. Alor. — **melolo** *melolo.* *Doh.* is a very distinct geographical form with light blue submarginal spots, which are almost united into bands, being proximally broadly diffuse, and only inappreciably and rarely centred with white. ♀ with traces of *eleusinida*-pattern. The under surface is the poorest in markings of all the *picina*-races, the hindwing commonly entirely without dots. Sumba.

E. watsoni *Moore* doubtless replaces *picina* on Buru in the Moluccas. Upper surface very dark, with *watsoni.* uniform deep blue reflection. Expanse very large. Forewing with small, narrow, reniform sabapical spots, predominantly white with light blue border. Hindwing with one or sometimes three likewise reniform, pure white subapical spots and rarely with white marginal dots. Under surface dark chocolate-brown with dull blue gloss. Forewing without minute marginal dots. Discal spots violet, arranged as in *picina.* Buru; rare.

E. dufresne *Godt.* is the oldest name for a species which inhabits the Philippines and is better known *dufresne.* under the name *laetifica Btlr.*, under which it has also been figured 82a. *dufresne* is characterized by a band-like, confluent row of four white subapical spots, which are bordered with brilliant light blue. In the submarginal area of the forewing moreover are placed four more or less white-centred rounded patches, the hindwing bearing three dots in the ♂, in the ♀ six to eight, gradually decreasing in size posteriorly. Hindwing as a rule with a further row of small white antemarginal dots. Under surface with blue cell-spot, two discal spots and a whitish streak at the submedian. Hindwing mostly without cell-spot, but with three to five ultracellular dots. The white subapical patches of the upperside strongly reduced, and the submarginal spots scarcely larger than the subterminal dots. — In one ♂ all the white spots, except the subapical ones, are absent beneath, and the submarginal patches of the forewing have also nearly disappeared, the blue reflection on the upperside is darker and duller than in normal examples, **azagra** *subsp. nov.* Habitat unknown. Mindoro (?). *azagra.* — **bazilana** *Fruhst.* is a considerably different race without distinct white subapical area on the forewing, *bazilana.* on the other hand with the submarginal spots almost equal in size and all centred with white: the cellular and discal spots of the under surface more pronounced than in *dufresne* from more northerly localities. Bazilan, February, March, discovered by W. Doherty. From the other Philippines a whole series of geographical branch-races may still be looked for. — **swinhoei** *Wall.* inhabits Formosa, where it appears not to be rare *swinhoei.* at Taihemoku near the south point of the island. Forewing with somewhat smaller, darker blue, but likewise all white-centred submarginal spots. Hindwing with three subapical patches and a row of pure white antemarginal dots, always strongly expressed. Under surface, also that of the forewing, with very small marginal and discal spots.

E. gloriosa, with the forewing 52 mm. in length, is the largest known *Stictoploea* and distinguished from all the other species in having the most extended white submarginal spots on the forewing. Two local
gloriosa. races: **gloriosa** *Btlr.* (= superba *Voll.*, badonia *Kirby*, schlegeli *Fldr.*) (84 b), from the north of Celebes, collected by me at Toli-Toli, November-December, near the sea-coast; a rapid flier, but like all the Euploeas is tempted to lengthened rests by flowering shrubs. ♀ as a rule with a proximal smaller, but pure white row of discal spots, which are united with the violet submarginal patches by diffuse proximal prolongations of the latter. Under surface with only slightly narrower rows of white, often wedge-shaped markings. Discal
pompilia. patches of the hindwing likewise whitish, not pale, as in the other *Stictoploea*. — **pompilia** *subsp. nov.* is the hitherto unnoticed form of Southern Celebes, recognizable particularly beneath by the reduced white spots, of which the discal ones are again tinged with light blue or violet. Observed by me at the Peak of Bonthain even at an elevation of 1000 m.

E. picina inhabits the Moluccas, and with its more dusky upper surface is absolutely the reverse of
inaequalis. the preceding species. Everywhere very rare, there are as yet only two island races to record: **inaequalis** *Btlr.* (81 b). Ground-colour of the hindwing as a rule somewhat lighter brown than on the figure, moreover the ♀ shows above a lighter brown distal margin. Under surface of the ♀♀ always with whitish grey anal area, which is sometimes reproduced on the upperside. Discal markings predominantly whitish, no trace of
picina. marginal dots Amboina. Saparoea, Ceram. Very rare. — **picina** *Btlr.* (= plateni *Stgr.*) is a form strongly darkened above and beneath, with more extended dark violet reflection on both wings and a slightly indicated light brown submarginal area on the upperside of the hindwing. Northern Moluccas, Batjan, Halmaheira: ♀ still undescribed. Described by Butler with the incorrect locality "Sumatra", but very recognizably figured.

E. doleschalli is the oldest designation of a Papuan collective species which passes in collections under a series of names, among which, however, the very one entitled to priority has been entirely ignored. Apparently in the whole range of the species striking deviations occur, which have given occasion to different specific names. But in spite of all the statements to the contrary, there is also in New Guinea as well as in India and on the Malayan islands only one *Stictoploea* in each district, which excludes the presence of a
doleschalli. second species. — **doleschalli** *Fldr.* (= papuana *Reak.*), the form from the Dutch region, was figured as *penelope Btlr.* (81 a), a name with which the type-form of the collective species is labelled at the British
moesta. Museum. — As **moesta** *Btlr.* an insignificant variety has been described, which bears only three blue-violet
inconspicua. subapical spots on the forewing. — **inconspicua** *Btlr.* is a form with dark brown upper surface and somewhat
aethiopina. lighter margins, especially on the hindwing, but without a trace of white or violet apical spots. — **aethiopina** *Sm.*, founded on two ♀♀, shows only a white costal spot on the forewing. — All these names refer to examples
immaculata. from Dutch New Guinea, whilst **immaculata** *Btlr.*, the race of the British region, is somewhat smaller than *doleschalli*, and still darker: only ♂♂ without white submarginal spots are known. Also according to Butler the
agema. ♀ has no submarginal marks at all. — As **agema** *subsp. nov.* we introduce the geographical race from Kaiser-Wilhelmsland, which is somewhat smaller than my examples of *doleschalli* from Sorong and Dorey, Rapsur and Hattam in Dutch New Guinea. The form *inconspicua Btlr.* is the typical form in Friedrich-Wilhelmshafen, but examples also occur which correspond to the figured *penelope*, and from Finschhafen I even have before
egregia. me ♂♂ with the submarginal patches of the forewing entirely white (**egregia** *form. nov.*). The ♀♀ of *agema*, of which, however, I have only received 5, are dark brown, with steel-blue tinge and rather sharply defined light brown distal border, with slight reddish sheen. At the proximal edge of this are placed six whitish, violet-powdered submarginal patches of unequal size, which in one ♀ remain pure white and are even continued on the hindwing. The ♂ figured shows an aberration, the forewing having three grey-violet intraneural
limbata. stripes. — **limbata** *subsp. nov.* has the forewing almost entirely black with extremely dark, indistinct blue gloss. Hindwing with broad, chocolate-brown distal margin, ♂ occasionally with a violet subapical dot on the forewing, otherwise belonging to the form *inconspicua Btlr.* ♀ resembling that of *agema*, but lighter brown, with indistinct,
tarnis. brown-powdered submarginal patches. Hindwing with almost whitish marginal area. Waigeu. — **tarnis** *subsp. nov.*, inhabiting the island of Jobi in Geelvink Bay, is even larger than *doleschalli Fldr.* from Sorong, and above, especially at the anal margin of the hindwing, darker than *limbata* from Waigeu. Under surface of both wings
amarynceus. with larger light blue discal patches than the allied races — **amarynceus** *subsp. nov.* is before me from the island of Salawatti and bears the most pronounced and irregular submarginal patches on the forewing. ♂ with the light brown anal margin more extended than in *limbata*. ♀ almost entirely light brown, marginal area
melander. on the underside of the hindwing in both sexes inclining to whitish. — **melander** *Sm.*, described from the island of Santa Cruz, appears also to belong to *doleschalli* as the most easterly offshoot known. ♂ brown with two narrow violet subapical patches on the forewing and four small white dots between the veins. Hindwing as in *limbata*.

palla. **E. palla** *Btlr.* (= payeni *Fldr.*) (84 b) replaces *doleschalli* on the Aru Islands. It only differs in having the inner margin on the underside of the forewing in both sexes cut off straight as above and all the white subapical spots somewhat reduced. Discal patches of the hindwing absent and only three present on the forewing

E. tristis *Btlr.*, a miniature form of the preceding, forewing similarly marked, but the submarginal ovals of the hindwing removed further proximad, narrower, under surface more copiously dotted with violet than *palla*, forewing with white, partly absent submarginal spots, but both wings with violet cell-patch and a row of five transcellular spots. New Hebrides, apparently rare. — **scylla** *subsp. nov.* is a race without submarginal punctiform spots on the underside of the forewing, and with only three distinct subapical white spots on the upperside. New Hebrides without more exact locality. *tristis.* *scylla.*

E. jacobseni *Röb.* (= wetterensis *Fruhst.*, baudiniana *Godt.* ? ?) (82 e) is a pretty species, which inhabits Micromalayana (Timor Group) and must be regarded as the smallest *Stictoploea* known. ♂: forewing with slight violet sheen on a dark ground, hindwing light brown like the upperside of both wings in the ♀♀. Forewing with very broad, pure white subapical patches, proximally slightly tinged with violet, and four prominent rounded submarginal spots. Hindwing with three rounded subapical punctiform spots. A form which probably belongs to the dry season is **crassimaculata** *form. nov.*, with very broad yellowish white submarginal band on the hindwing in both sexes, recalling *orope* and *fabricia*. Wetter. — **timora** *Fruhst.*. ♂: ground-colour of the forewing a very dark, of the hindwing a somewhat lighter brown. From the apex to the anal angle runs a row of large white spots, which are proximally bordered with violet. The three upper spots are placed close together, the others being smaller and isolated. The yellowish white submarginal spots of the hindwing, as in *sylvester*, are distally separated by a brown tooth projecting from the distal border, and are proximally somewhat incised, especially in the ♀. Both wings are bordered by a marginal row of white dots. Above the end of the cell the ♂ bears one violet dot, the ♀ three white ones at the costal margin. Of the two silky, very narrow sexual stripes the upper one is $^1/_3$ shorter than the lower and both are much smaller than in *sylvester*. The brown ground of the under surface, which gradually becomes lighter from the base to the distal margin, recalls *orope Bdv.* and *oropina Röb.*: a colouring which combined with abundant white bands lends to the Euploeas of the small Sunda Islands a characteristic stamp. On the under surface of *timora* all the markings of the upperside are reproduced, and in the middle of the wing there is further a row of blue-white dots. On the forewing 4 of these spots are costal, 1 cellular, 3 circumcellular, and 1 or 2 placed below the submedian: the hindwing bears 1 cellular and 6 circumcellular dots. One dot is placed at the base of the forewing and 4 at that of the hindwing. Antennae and abdomen as in *sylvester*. Length of the forewing: ♂ 41 mm., ♀ 34 mm. Timor. *jacobseni.* *crassimaculata.* *timora.*

E. pelor *Dbl.*, an extremely rare species described from Australia, but never found there again. As I have a ♂ before me from Babber, the Timor-Laut Group is pretty certainly the true locality of the species. Upper surface, except for the two sexual stripes, exactly as in *sacerdos* (84 d), only with two spots instead of a costal patch on the forewing. Under surface as above, but with four transcellular and three discal small violet spots on the forewing and a cell-dot and six small blue-violet discal spots on the hindwing. Ground-colour deep black. *pelor.*

E. rogeri *Hbn.* is an allied species, likewise very rare, which differs from *pelor* in the smaller white submarginal spots on both wings. Locality unknown, probably islands of the Timor or Timor-Laut Group. *rogeri.*

E. sylvester *F.* (= dardanus *Misk.*) resembles *eichhorni Stgr.* (81 c) except for the two scent-stripes. Under surface exactly as in *pelor*. — As **crithon** *Misk.* a form has been described of which it is doubtful whether it is an accidental aberration of *sylvester* or must be regarded as a distinct but very rare species. Upper surface deep black with purple sheen and two sexual spots, under surface dark brown with lighter margins. Forewing beneath with two blue-white, hindwing with five violet punctiform spots. Like *sylvester* at Cape York, North Australia. *sylvester.* *crithon.*

Group Trepsichrois.

Larva with four pairs of very long appendages. Cell of the forewing as in *Crastia*. Hindwing with large androconia-patch and a small spot covered with yellow, shaggy, clubbed scent-scales with short cilia. Anal pencil somewhat shorter than in *Stictoploea*, longer than in *Crastia*, light canary-yellow, simple, can be easily and strongly moved and projected. Valve not examined as yet. The group does not extend eastward beyond Celebes, and hence is purely Indo-Malayan, only one species *(mulciber)* has been observed in New Guinea, as an accidental importation. Of all the Euploeids the species of this group all have in both sexes a smell most repulsive for human organs.

E. mulciber is better known under the designation *midamus L.* and as such also figured vol 1. pl. 28 e and described with larva and pupa p. 78. The species belongs to the characteristic butterflies of India, but strange to say is wanting in Ceylon and the Andamans, though it is met with again on the Nicobars as an occasional migrant. Northwards it extends to Formosa, eastwards to the island of Bali, and is broken up into a series of local races, some of them highly specialized. It is further worthy of note that there is a series of butterflies and of Chalcosiids which have a convergent garb and afford striking examples of mimicry. Even specimens of the Nymphalid genus *Penthema* and some Papilios of the *paradoxus*-group, which are much larger than the model, resemble *mulciber* on the wing to such a degree that they deceived me over and over again, and my Annamites and Japanese could not distinguish them at all. — **barsine** *Fruhst.* is the largest *barsine.*

race known, both sexes distinguished by unusually large subapical patches with well developed white centres on the forewing, but in the ♀ the influence of the island melanism is shown by the white stripes of the hindwing being very thin and occasionally entirely absent in the cell. Formosa, up to 4000 ft., on the wing
mulciber. especially July—August. — **mulciber** *Cr.* (= midamus *auct.*, linnæi *Moore*), described from China and the Coromandel Coast, inhabits the whole of continental South Asia from China and Tonkin to Singapore, and is met with from the sea-coast up to 2000 m. wherever there are flowering shrubs and trees to attract it. In the north-western Himalayas it is already rare. According to the season there occur very small examples (Siam, January) and strikingly large specimens (Tonkin, Assam, July). According to my observations the anal pencils are pushed out with nervous haste and drawn in again just as quickly, and at the same time an
kalinga. extremely pungent smell is emitted, which is also present in the ♀♀. — **kalinga** *Doh.* is a name given to a race from Southern India which I have not seen, and which moreover is synonymous with *claudius F.* if the locality "Tranquebariae" of Fabricius should prove to be correct. According to the description *kalinga* differs from *mulciber* in the ♂ only in having less blue reflection on the forewing, which bears larger white patches, and in the somewhat smaller sexual spot on the hindwing. The ♀ is said only to differ from the ♂ in the absence of the sexual spot on the hindwing and of any trace of white longitudinal bands in the cell.
vandeventeri. Hitherto only known from the Ganyam District near Madras. — **vandeventeri** *Forbes* can only with difficulty be separated from continental *mulciber;* but if large series are compared, West Sumatran examples in particular can be distinguished by the more pronounced white dotting of the forewing in the ♂♂ and the more extended adneural striation of the hindwing in the ♀♀. *vandeventeri* is the commonest *Euplœa* of the alluvial plain of Sumatra, where it flies all the year round, one generation following another continually. Banka, Billiton (?).
verhuelli. — **verhuelli** *Moore* differs from the Sumatran sister-race in the considerably enlarged white subapical wedge-spots, slightly margined with blue, and the entire absence of the discal patches of the forewing. The ♀ likewise bears large subapical white smears, which are continued as rounded patches in the middle of the wing. Nias.
maassi. — **maassi** *Hag.* is a still very rare race from the Mentawej Islands with only one row of light blue round (apically not wedge-shaped) submarginal spots on the forewing. ♀ pale brown, without a trace of a blue
batunensis. reflection, the interneural stripes somewhat tinged with brownish. — **batunensis** *Fruhst.* (= nidana *Fruhst.*) is the darkest island form which is yet known from the Sumatran region. In *batunensis* the blue ground-colour of the upper surface is darkened; the white marginal dotting of the hindwing is entirely absent and on the forewing we only notice four rather dark blue submarginal spots and some indistinct admarginal dots. The dotting of the under surface is likewise reduced, especially the small circumcellular blue spots on the hindwing. The forewing bears below the cell between the middle median and the submedian peculiar grey scent-scales (corresponding with the friction-spot on the upperside of the hindwing), which in other forms of
malakoni. *mulciber* are tinged with yellowish. Batoe. — **malakoni** *Doh.* again approaches in appearance the Sumatran form, as it bears two rows of submarginal light blue patches on the forewing and the usual cell-spot. The ♀ is above brown throughout, the subapical patches obsolescent, dusted with brown, forewing without trace
basilissa. of a blue or violet tinge. ♂ not rare in April on the Island of Engano. — **basilissa** *Cr.* (85 a) is a typical Javan butterfly and on account of its abundance one of the most striking species among the Lepidoptera of the island. Particularly in the heaviest rainy season *basilissa* sometimes occurs in many thousands, thus in January-February 1892 in the Bay of Palabuan, where in the open forest and at the edge of the woods, together with *Radena juventa,* they were so abundant that it was difficult to catch the better species. No other local race has the subapical blue reflection so sharply defined, so large a white spot before the apex of the cell or so strong a submarginal double row of white patches on the forewing and such pronounced white striation on the hindwing as *basilissa.* The latter characters are even somewhat more pronounced in the race from Bali. Very common near Batavia and on Bawean (July—September). In West Java occurs an interesting but rare ♀-form, which forms the transition to *malakoni Doh.* and *maassi Hag.,* shows no trace of blue sheen on the forewing above, darkened white bands on the hindwing and a reduction of the rounded
donada. patches on the forewing, and is apparently only found in the rainy season (f. **donada** *form nov.*) (85 a as
portia. *basilissa*). Palabuan. Batavia. — **portia** *Fruhst.* approximates very nearly to *malakoni Doh.* in the strongly reduced blue dotting of the forewing compared with *basilissa;* the ♀ shows somewhat blue reflection on the forewing, but differs both from the Javan and the Sumatran race in the insignificant white adneural striation
paupera. of the hindwing. North and South Borneo, Natuna Islands. — **paupera** *Stgr.* approaches the continental *mulciber* in the large light blue spots of the forewing, but the submarginal patches have no white centres; the ♀ as in *malakoni* and *donada* without trace of a violet or blue tinge and only differing from the figured *donada*
mindanaensis. in having the white interneural areas of the hindwing somewhat broader. Palawan, rather rare. — **mindanaensis** *Semp.* ♂, upper surface of fore- and hindwing, so far as the latter is not occupied by the furry spot, with brilliant steel-blue gloss; at the distal margin of the forewing a proximal row consisting of 8 larger blue dots and a distal row composed of 12 smaller ones which are not much subject to variation. Under surface: on the forewing there are sometimes some blue dots present at the costal margin in addition to the two usual rows of blue marginal dots and the 2—3 placed on the middle of the wing: the hindwing bears, besides the distal row composed of 14 dots, a proximal row of 12 or less, of which the 8 placed next to the inner angle are elongate, streak-like, the others round and occasionally bipartite. The ground-colour is darker

than in the preceeding forms, the colour of the markings the same except for the dot placed between the 1st and 2nd median veins, which is reddish. ♀: upper surface with strong blue reflection on the distal half of the forewing; very constant and varying but little in the size of the white spots; on the forewing the light streaks in the cell next to the base and at the inner margin only slightly indicated, really only showing through from the under surface, which in addition to the absence of the blue reflection only differs from the upperside in the presence of the whitish streaks just mentioned. — **seraphita** *Fruhst.* (81 d) has shorter and more rounded wings than *mindanaensis* and stronger rows of blue dots on the forewing and hence somewhat recalls *gelderi Snell.* Hindwing above darker than in Mindanao ♂♂. On the under surface of the wings all the patches and streaks are enlarged and purer blue. Hindwing further with a cellular and several circumcellular strigae. ♀ with more extended and more intensive white markings and in the cell of the forewing a broad basal stripe, which is wanting in *mindanaensis.* Bazilan, February, March, discovered by W. Doherty. — **megilla** *E.* (81 d, ♂, 85 e ♀) is so far removed from the *mulciber*-type that one would be tempted to regard it as a species if it were not connected with *mulciber* and *paupera* by transitional forms such as *kochi Semp.* As the larva also, according to Semper, only shows unessential differences from the continental Indo-Malayan collective species, *megilla* is united with *mulciber* in spite of the different colouring and markings. The ♂ is easily distinguished from the other species of *Trepsichrois* by the large white spot at the apex of the forewing, which as a rule consists of two large and four small spots, of which, however, the latter are frequently suppressed. On the upper surface there are in addition sometimes bluish marginal spots, the distal ones being small and the proximal ones very few in number and somewhat larger, for the rest the forewing is unicolorous with brilliant steel-blue reflection. The anterior half of the hindwing is occupied by the grey-black furry hairs peculiar to this genus, bounded basally in the cell by the characteristic small gold-brown spot. The proximal half of the hindwing, together with a narrow distal margin reaching to the 1st subcostal vein, is unicolorous and iridescent like the forewing. The under surface is unicolorous brown as in all the species of this genus, in addition to the large white patch at the apex of the forewing, which is always divided into six spots, there is mostly at the distal margin of both wings a row of small blue dots as well as sometimes 1—3 similar dots before the cell of the forewing. A somewhat larger reddish spot at the median nervure between its 1st and 2nd bands is always present and also the grey furry dusting at the inner angle of the forewing, likewise basally bounded by a small yellow-brown spot. The under surface of the ♀ is lighter brown than the upper and without iridescence. The larva eats white and red oleander flowers; it has two horns each on the segments before and behind the four pairs of forelegs and two each on the 2nd and 3rd thoracic segments. It is transversely striped with black and white, but this black colour, as also that of the similarly coloured tentacles, more inclines to reddish. The pupa is entirely golden, like a polished gold plate, the wing-cases with a somewhat silvery sheen. The pupal stage lasts 10 days in July. Luzon. — **kochi** *Moore.* ♂, upper surface: this race from the western Visayas differs from the other Philippine *mulciber*-races in having seven bluish spots on the middle of the forewing, besides the two very large and distinctly expressed rows of bluish spots at the distal margin. The brilliant blue reflection is extended over the whole of the forewing as well as over the part of the hindwing placed next to the furry patch, where, however, it is weaker than on the forewing. On the under surface there are further some blue dots at the costal margin and in the cell of the forewing and the distal-marginal dots are more sharply expressed than in *visaya,* with which the underside otherwise exactly agrees. Of the blue streaks placed round the cell of the hindwing in *mulciber* only in one example of *kochi* a slight indication is present, but in accordance with the geographical position this form is nearest to *portia Fruhst.* from Borneo.

seraphita. *megilla.* *kochi.*

E. semperi is divided into two geographical races. In **semperi** *Fldr.* (= tisiphone *Btlr.*) (85 e), from Mindoro, the ♂ is easily distinguished on the upper surface from the other species of this genus by the absence of the blue reflection, of which only a slight dark violet tinge is present on the proximal half of both wings. The four to five violet-white dots at the apex of the forewing are occasionally suppressed except for one placed 6 mm. before the distal margin between the last subcostal and the discoidal veins. Under surface: occasionally there is a small bluish white dot in the cell of the forewing. *semperi* differs from *megilla* from Luzon in the absence of the large white spot at the apex of the forewing, from the forms from the Visayas and Mindanao in the bluish white dots. ♀: upper surface distinguished from the races of the other Philippines by the entire absence of the blue reflection and also by having the proximal row of spots at the apex of the forewing removed somewhat further from the distal margin. The under surface is similar to the upper, but with somewhat lighter ground-colour. — **visaya** *Semp.* ♂, upper surface: the violet-blue reflection is only present on the distal half of the forewing, whilst the proximal part of the hindwing, which is not occupied by the furry brown spot, is light brown. Hence this subspecies, which only flies on the eastern Visayas, differs from the very nearly allied *semperi* from Mindoro in having the blue reflection on just that part of the upper surface from which it is absent in *semperi*, and vice versa. The light blue distal and proximal rows of spots at the distal margin are very variable, varying from twelve distal and seven proximal dots to almost complete absence. The under surface is distinguished from that of the preceding species by having the dots in the middle of the wings and at the distal margin blue and

semperi. *visaya.*

the proximal row placed nearer to the distal margin at the apex of the forewing; as on the upper surface the number of dots is very variable. The ground-colour is uniform brown, as in *semperi Fldr.* and *kochi Semp.* ♀, upper surface: on the distal half of the hindwing there is a very slight blue reflection: the proximal row of distal-marginal dots is placed nearer to the margin than in *semperi*. The size of the white spots on the middle of the wings, as well as the size and number of the marginal dots, is very variable: some spots occasionally tinged with blackish. On the hindwing the light markings are always tinged with blackish. The under surface is without blue reflection and has the ground-colour somewhat lighter. Cebu, Bohol, Camotes, Samar, Leyte, Panaon.

The range of **E. gelderi** begins in Micromalayana, where the continental *mulciber* reaches its eastern limit in Bali with *basilissa Cr.* This species is everywhere rare and inhabits Flores, Sumbawa, Lombok and some satellites of the two first-named main islands, and flies at elevations of about 5—800 m. above the sea. The ♂♂ with brilliant yellow scent-pencils, which emit a very strong smell somewhat recalling mignonette. Four insular branch-races: **gelderi** *Snell.* (85 e ♂), described from Flores; ♀ larger than the ♂ figured, with the yellowish white patches and bands of both wings more than twice as broad. — **dongo** *Doh.*, described from Sumbawa, scarcely differs in the ♂ from the preceding; ♀ above with no trace of a blue tinge, with a pale basal streak in the cell of the forewing and a rounded spot before its apex. Under surface with all the strigae white and sharply defined. Very scarce in the mountains of Sumbawa. — **phoebadis** *subsp. nov.* is a smaller and darker race from Lombok, chiefly characterized by the melanotic ♀, which was erroneously figured 85 e as *gelderi*-♀. As may be seen from the figure, all the white bands are reduced in extent, the cell-streak of the forewing is almost entirely suppressed and the stripes of the hindwing are covered with brownish. Rare on Lombok, always at the edges of woods and singly on flowering underwood. — **elwesi** *Doh.*, of which only ♀♀ are as yet known, was discovered in the interior of Sumba at an elevation of about 1000 m. ♀ above brown, cell of the forewing as in *dongo*, otherwise the markings arranged as in *Radena oberthueri Doh.* Not known to me in nature. According to Doherty it is entitled to specific rank.

gelderi. *dongo.* *phoebadis.* *elwesi.*

E. euctemon *Hew.* is the most sharply defined species of the group *Trepsichrois* and distinguished from all the other species by a yellow scent-area more than three times as broad and the absence of grey or black patches of androconia on the hindwing. It is at the same time the only species in which the ♂♂ (85 a) are adorned with blue submarginal patches on the hindwing, and in the entirely different ♀ (81 d), which much more resembles a Danaid *(Nasuma)*, *Trepsichrois* reaches in *euctemon* the maximum of sexual dimorphism. Thus it came about that the learned Felder described the ♀ as a new species under the name of *configurata*, and Moore even based two genera on the two sexes (*Bibisana* and *Glinama*). The species is rare in Celebes; I myself took both sexes in the heaviest rainy season, January, in the hinterland of Macassar. Typical ♀♀ from Tondano in the Minahassa are somewhat smaller and more broadly suffused with brownish than South Celeban examples.

euctemon.

Group Euploea *F.* 1807.

Larva only known of two species, of which the western one bears 3 pairs of tentacles *(corus)*, the eastern, judging from a figure, only 2, supposing that the figure is correct. Cell of the forewing without recurrent vein *(Calliploea)* or only with rudiments of one *(Euploea)*. The first subcostal vein sometimes coincident with the costal *(Calliploca)*. Upper discocellular of the forewing present. Anal pencil yellowish. Hindwing with large scent-patch, but forewing without sexual spot.

a. Subgroup Calliploea *Bthr.* 1875 (= *Tabada Moore* 1883).

Small species with rounded forewing. Larva unknown,*) which is much to be regretted, as the separate species are very difficult to define, owing to their variability and the partially discontinuous distribution. Moreover on some islands of the Philippines and parts of Micromalayana the offshoots of two species seem to occur together, whilst the Macromalayan. Islands, including Celebes, are only inhabited by one species. The division of the species is here attempted exclusively from a geographical point of view and is consequently an arbitrary and provisional one, but with our present knowledge the only way out from the labyrinth of names. Valve scarcely different from that of the group *Salpinx*, very narrow, distally only slightly convex.

E. mazares is the species of the group which has advanced furthest towards the west, representatives of it inhabiting all the archipelagos from the Solomons to Sumatra and Formosa. — **ledereri** *Fldr.*, somewhat larger even than *mazarina* (80 d), has the same anal brown patch in the submarginal area of the forewing as *mazarina* and differs from it in the relatively large light blue cell-spot and circumcellular patches of the forewing. Common on the Malay Peninsula, it is occasionally met with in southern Tenasserim and the Mergui Archipelago as a great rarity. — **eunus** *Nicév.* differs from *mazarina* in the uniformly light brown upper surface of the forewing, the lighter submarginal patches with violet instead of blue margins and the smaller transcellular spots of the forewing, which are arranged as in *ledereri*. The ♀♀ are unusually rare. According to Martin the form does not ascend above the lowest hills of North-East Sumatra, and is commonly

ledereri. *eunus.*

*) See Appendix p. 272.

found in company with *Danais hegesippus* and *Crastia distanti* at river-banks and shows a decided partiality for the neighbourhood of the sea-coast. — **mazarina** *Fruhst.* (80 d) closely approaches *mazares* from Java and differs from *emms* in the absence of cellular patches and in the larger subapical spots of the forewing with purer white centres. West Sumatra. No representative forms are yet known from the satellite-islands of Sumatra. — **mazares** *Moore*, the name-type, from Java, is the commonest *Euploea* of the island at elevations of about 500 m. and both in the east and west occurs up to many thousands, especially in the rainy season from January to April at suitable places, neglected coffee-gardens and the edges of woods and is particularly fond of herbs. West Javan specimens bear more extended spots on the forewing, proximally bordered with a beautiful light violet. The costal spot of the forewing is occasionally absent, otherwise the variation consists in the lesser or stronger development of the submarginal patches. In contrast to *emms* ♀♀ are by no means rare. *mazares* from Bali and Kangean are not known to me in nature. Incredible as it may appear, the island of Bawean, though only a few sea-miles distant from Java, just as it produces a distinct race of *E. crameri*, has also a *mazares*-race of its own, **baweana** *Fruhst.* (83 d), recognizable by the very broad (much larger than in the figure), predominantly white submarginal spots on the forewing, proximally margined with light blue, and by the darker, brighter and more uniform steel-blue reflection on both wings. Forewing beneath more prominently dotted with white than in *mazares*. — **lombokiana** *Fruhst.* has the darker ground-colour and the very strong blue-violet reflection of the upperside in common with *baweana*, whilst beneath the satellite-island character is revealed in the reduction of the white dotting. That is to say the admarginal dots are completely suppressed in most examples and the submarginal dots are not only fewer but also smaller. Moreover the white pupils on the upperside of the forewing are less noticeable on account of the uniform dark violet tinge of the submarginal patches. Lombok, where from April to June it is an ornament among all the wealth of flowers at about 600 m. and together with *Danais melissa* is among the visitors to the village gardens. — **sambavana** *Doh.*, larger than *lombokiana*, nevertheless has essentially smaller submarginal spots on the forewing, with diminutive white dots, and the spots on the under surface likewise insignificant. Doherty has already observed that in this form the first subcostal vein is occasionally coincident with the costal, as in *Radena, Ideopsis* and *Hestia*, a phenomenon which is also repeated in *mazares*. — **philinna** *Fruhst.*, very near to *sambavana*, is somewhat inferior to it in size, but in spite of its smallness has larger light blue submarginal patches on the forewing. The marginal area of the hindwing lighter brown, the submarginal spots very large, forming a transition to *wetterensis* (83 d). Islands of Adonara, Pura and probably also Flores. — **sumbana** *Doh.*, a strongly marked race, almost entitled to specific rank. Forewing as in *wetterensis* (83 d), but with more extended light violet proximal bordering, which is absent in *wetterensis*. Hindwing without any white spots, under surface very striking, without a trace of admarginal dots, but with white subapical patches on the forewing united into a broad band and a submarginal row of 6—7 rounded punctiform spots on the hindwing. White markings of the ♀♀ still more striking, recalling *tullius F.* from Australia. Sumba, not rare. — **natunensis** *Fruhst.* is a very small race, above dark with bright steel-blue sheen, with light blue submarginal spots on the forewing, which are distinctly but only delicately dotted with white. Under surface dark chocolate-brown with a slight violet sheen and relatively large, round, light blue-violet discal spot on the forewing. Natuna Islands. — **aristotelis** *Moore*, described from Sandakan, but in my collection also from the neighbourhood of Labuan and the Sultanate of Brunei, is a larger form with intensive light blue reflection on both wings, and mostly very small white, blue-margined submarginal spots on the forewing. Only a few examples show a diffuse light blue bordering to the patches of the forewing. — **palawana** *Fruhst.* approaches the preceding, but has the dull part of both wings more extended and hence the blue reflection restricted, and always reduced submarginal spots on the forewing, which as a rule can scarcely be called more than punctiform. Palawan, January. — **monilina** *Fruhst.* on the other hand is a retrogression to the most copiously blue-spotted subspecies of the Sunda-Islands, the white spots are margined with broadly diffuse and more extended blue-violet. The under surface is, however, scarcely more strongly dotted with white than in *palawana*. February, March. Bazilan. — **monilis** *Moore* inhabits the northern Philippines. The extent of the white spotting reaches the maximum of its development in this race, even the hindwing as a rule bearing small white submarginal dots. Babuyanes, Negros, apparently flying all the year round and according to Semper somewhat liable to variation.

mazarina. *mazares.* *baweana.* *lombokiana.* *sambavana.* *philinna.* *sumbana.* *natunensis.* *aristotelis.* *palawana.* *monilina.* *monilis.*

E. koxinga *Fruhst.* (= klugi Mats. ?) (83 c), distinguished by considerable size, extraordinarily brilliant blue reflection, large white submarginal patches on the forewing with light blue margins, which, moreover, are suffused with a restricted light reflection, which is reproduced in the figure. The under surface is characterized by a double row of distinct small white submarginal dots. Formosa, ascending form the plains to the spurs of the mountains and nowhere rare from March to July.

koxinga.

E. mariesis *Moore* I have not seen in nature; according to the description it approximates to *mazares*, but is darker coloured on both wings and has the submarginal spots twice as large and proximally bordered with blue. Hindwing with a row of small but distinct white dots, which are continued to the anal angle. From the Lu-shan, near Kiu-Kiang, Central China. Perhaps *koxinga* should be united with it as a subspecies.

mariesis.

E. tulliolus differs from the *mazares*-group in the broadened white apical spots of the forewing and as a rule in the sharply expressed proximal row of submarginal dots on the hindwing beneath, but the latter disappear in the examples from the northern Philippines. Where forms of *tulliolus* occur together with those of *mazares*, one might be tempted to regard the former as extreme dry-seasonal products of *mazares*. Moreover, in New Guinea the differences are completely effaced and also on the South-Sea Islands races of *tulliolus* intergrade with those of *adyte Bdv.* from New Caledonia. — *pollita.* **pollita** *Eschsch.* is regarded as the most northerly offshoot of the species and bears as a rule even broader white bands on the forewing than on the figure, which was taken from an example from Mindanao. Typical *pollita* have no white markings at all on the hindwing, and on its grey-brown under surface even the small admarginal dots are absent. North Philippines, especially Luzon. — *ecbatana.* **ecbatana** *subsp. nov.* (85 d, as *pollita*) inhabits the southern Philippines, Mindanao, Bazilan and other islands. Hindwing on both surfaces with prominent submarginal rows of white dots. ♀: beneath with narrower white subapical band than the ♂ type from Bazilan. Flies in February-March, thus taken at the same time as *mazares monilina Fruhst.* — *tulliolus.* **tulliolus** *F.*, the name-type, has decidedly dark reflection, more steel- or violet-blue than light blue, on the upperside of both wings, more distinct submarginal spots but narrower subapical bands on the forewing. Common in Queensland from Brisbane to Cape York. — *sicinia.* **sicinia** *Fruhst.* is a geographical form from the island of Dammer, like *tulliolus* without white submarginal band on the hindwing and with the subapical patches of the forewing much reduced — *meda.* **meda** *Fruhst.*, from the island of Pura to the east of Sumbawa, is throughout lighter blue than *tulliolus*, forewing with very broad bands, hindwing with white submarginal spots, which are also distinct beneath. — *turneri.* **turneri** *Btlr.*, from Darnley Island to the north of Australia, which is unknown to me, forms a transition from *tulliolus* to *saundersi Btlr.* from Arua in that the subapical band of the forewing is exactly intermediate betwen those of the two branch-races mentioned. *turneri* was described from a ♀. — *saundersi.* **saundersi** *Btlr.* is a common *Euploea* on the Aru Islands, dark blue in its general colouring, with pure white, medium-sized, submarginal spots on the forewing, which are proximally only slightly tinged with violet and beneath are likewise prominent, being somewhat larger than a pin's head. — *nocturna.* **nocturna** *Fruhst.*, from Salawatti, is larger, still darker violet-blue with deep steel gloss and on the underside of the hindwing also with distinct white patches. — *mardonia.* **mardonia** *Fruhst.* inhabits British New Guinea and occurs also in the German territory in the neigbourhood of Finschhafen. Upper surface with brilliant light steel-blue reflection, lighter than in *saundersi*, the small white spots with thin light blue border. Under surfare as in *saundersi*, hindwing with 2 rows of white submarginal dots. — *doryca.* **doryca** *Btlr.* probably replaces *saundersi* in all parts of Dutch New Guinea and is the malanotic extreme of the whole series of forms. Upper surface more violet than steel-blue with duller reflection, the light blue submarginal patches only slightly dotted with white. Submarginal and admarginal dots of the under surface mostly absent, and even the subapical row but little prominent. Dorey, Sorong, Hattam, Kapaur, everywhere common. — *offaka.* **offaka** *Fruhst.* is a smaller island race with the usual darkened colouring, submarginal patches of the forewing almost without white centre, their bordering more blue than violet and all the white dots of the under surface reduced, especially those of the hindwing. Waigeu. — *forsteri.* **forsteri** *Fldr.* is certainly the representative of *tulliolus* on the Fiji Islauds; upper surface lighter than in *doryca*, the markings of the forewing somewhat as in *saundersi*, broadly white, with narrow light violet proximal border; hindwing above without puntiform spots. Forewing with the patches sometimes larger, sometimes smaller, apparently varying according to the season; in the three ♀♀ before me they are smaller than in *saundersi*, under surface as in *saundersi*, but with the white markings somewhat more delicate. Viti-Levu.

adyte. **E. adyte** *Bdv.*, of which I saw the type at Ch. Oberthür's, probably also belongs to the *tulliolus*-series of forms. Upper surface of the forewing with a complete row of seven violet submarginal spots, only slightly touched with white, which beneath on the contrary are pure white and relatively large. Hindwing with a curved row of six to seven larger, pure white rounded submarginal patches, which decrease in size from the costal margin to the anal angle. Both wings with small admarginal dots. Forewing without discal white or violet spot, a characteristic, however, which may be either present or absent in all the allies of *tulliolus* discussed. New Caledonia.

seriata. **E. seriata** *H.-Schäff.* should perhaps be united with *adyte.* Upper surface lighter brown, almost without violet sheen. Submarginal spots of the forewing only slightly widened, nearly obsolete. Hindwing with distinctly defined yellowish brown marginal area. Under surface of both wings basally dark brown, lighter in the distal part. Submarginal dots of both wings pronounced, but yellowish instead of pure white. Admarginal streak-like dots on both wings. Forewing beneath without discal white spot. Islands of the Loyalty Group: Lifu, Uvea.

dudgeoni. **E. dudgeoni** *Sm.* (30 e), which occurs together with *doryca* at Humboldt Bay, Dutch New Guinea, was recently sent to me from Friedrich-Wilhelmshafen, where it seems to be the only blue *Calliploea*, whilst from Finschhafen I have only received *tulliolus mardonia Fruhst.*, but never *dudgeoni. dudgeoni* is distin-

guished by the duller brown ground-colour, which is lighter in the distal part, especially on the hindwing, the almost imperceptible blue reflection, in the ♀ in fact no longer present at all, the pale violet, diffuse marginal patches, in the ♂ without white centres, and particularly beneath by the absence of all the white subapical bands or spots so distinct in *tulliolus* and *doryca*. Most examples bear only a blue-white cell-spot on the forewing and some submarginal splashes on the hindwing. In the ♀ the submarginal spots of the forewing are inappreciably suffused with white and bear distally a small patch extending to the terminal margin.

E. hyems, decorated on both wings with brilliant white bands, is one of the most beautiful species and in common with *Crastia orope Bdv.* and *Stictoploea jacobseni Röb.* is a characteristic butterfly of Micromalayana, where it replaces *E. mazares Moore,* beginning to occur where the most easterly forms of *mazares* reach the limit of their range with *sumbana Doh.* — **wetterensis** *Fruhst.* (83 d) has a dark violet reflection on a dark brown ground, which on the hindwing also covers the white submarginal band of the ♂♂ as a light violet gloss. Underside as above, only with a row of very strong white submarginal dots, which adorn the butterfly together with the pure white, broad, subapical and submarginal spots and are so easily distinguished from allied forms of the *mazares*-series. Wetter, not rare. — **hyems** *Btlr.,* described from Timor, is somewhat larger, the ground-colour lighter and the white bands even more strongly expressed than in *wetterensis.* Only Butler's type in the British Museum is known to me. — **liza** *Fruhst.* (82 d) inhabits Babber and on the underside of both wings is dark brown with less violet reflection than *wetterensis,* yellowish white band on the forewing and a row of more extended submarginal patches on the hindwing which are rather quadrate than rounded, this being especially noticeable in the ♀♀, the submarginal part of which in *wetterensis* is as a rule entirely without markings. — **catilina** *Fruhst.* (80 d), from Dammer, has the violet reflection on the forewing as bright as in *hyems* and the white bands even broader. — **leaina** *Fruhst.* (85 d) is distinguished by the very distinct violet bordering of the white subapical bands of the forewing, the white area of the hindwing is extended to the distal margin, of which only a narrow stripe remains brown-black. Kisser. — **aga** *Fruhst.* (83 d) has the white spots on the forewing almost twice as broad and a still more extended pure white marginal area on the hindwing, in which beneath even the small brown intraneural spots are paler and begin to disappear. Letti, taken by W. Doherty in July 1892. — **kuehniana** *Fruhst.* (85 d), which is almost entitled to specific rank, shows diffuse elongate submarginal patches, proximally dusted with light violet and in the central part separated by broad black vein-stripes. Hindwing without sharply defined white band, but with whitish distal area, which proximally shades off into the light brown ground-colour. Under surface light brown with relatively very small subapical patches on the forewing. Roma, discovered by H. Kühn.

wetterensis.

hyems.

liza.

catilina.

leaina.

aga.

kuehniana.

E. visenda forms the natural continuation of the preceding species and is distributed over the very limited region of the Tenimber and Key Islands. Ground-colour black-brown with lighter brown under surface. Submarginal bands of the wings differing in width according to the local race, but always well developed. — **visenda** *Btlr.* occurs exclusively on Timor-Laut (Larat), above very similar to *aga,* differing from it in the broader black-brown distal border of the hindwing and the larger subapical yellowish white bands of the forewing. ♀♀ of the dry-season form are sometimes light grey-brown on the underside of the hindwing and the white area extends to the cell. — **ornata** *Fruhst.,* from Key, differs from *visenda* in the narrower, slightly yellowish white bands and spots, especially of the submarginal band of the hindwing, which consequently appears removed further proximad. The subanal patches of the forewing smaller than in *visenda* and *aga* (83 d), ground-colour of the under surface in the ♀♀ also more red-brown than in *visenda*-♀♀. Common everywhere on all the Key Islands and very variable, especially in the size. — **lonia** *Fruhst.* (85 d) very nearly approaches *ornata* and differs from it in having the white bands even narrower, particularly on the hindwing. Babber. In all the races of *visenda* there is no trace of a violet tinge on the upperside of the wings.

visenda.

ornata.

lonia.

E. menamoides *Fruhst.* (83 d), from Babber, is in certain respects an intermediate form between *hyems,* which is represented on Babber by *liza Fruhst.* (82 d), and *visenda Btlr.*, represented on the same island by *lonia Fruhst.* (85 d). It has in common with *liza* the violet tinge, particularly on the forewing, with *visenda* the arrangement of the yellowish white bands, which are nowhere bordered with blue-violet. But both ♂ and ♀ differ from *liza* and *lonia* in the smaller white subapical spots of the forewing.

menamoides.

E. hopfferi is one of the most distinct species of the eastern Moluccas and Key Islands, of which so far two island races are known, but of which quite a series remains to be discovered in the near future. — **hopfferi** *Fldr.* is a faithful copy of *eurypon Hew.* (86 e), from which, however, it is easy the distinguish by the projecting, excurved inner margin of the forewing, the *Calliploea* scent-patch of the hindwing and by having the white margining of both wings even broader and deeply incised proximally and hence more irregular. Costal area of the hindwing beneath with three large, sometimes confluent white spots, whereby the ♀♀ of *hopfferi* are distinguishable from those of *eurypon*, in which these costal patches are absent. Key Islands. — **helia** *Fruhst.* closely approaches *hopfferi*, but is distinguished by the light brown ground-colour

hopfferi.

helia.

and by the more yellowish instead of pure white borders of the wings, which in many examples completely shade off into the brown basal colouring. In one ♀ even the white band of the forewing is suppressed except for the vestiges of a subapical light patch. Banda.

niveata. **E. niveata** *Btlr.* combines the characters of the *tulliolus*-group with those of *hopfferi*, as the brilliant violet glossy forewing has the white markings somewhat more restricted than in *tulliolus*, but the hindwing has the white submarginal bands almost as broad as *hopfferi*. Under surface altogether as in *tulliolus*, only with extraordinarily broad, pure white submarginal area on the hindwing composed of quadrate spots. Queensland, apparently rather rare.

darchia. **E. darchia** *Mac-L.* (= priapus *Btlr.*) is very rare in the same country and is not known to me in nature. Forewing similar to that of *tulliolus*, but the white spots united into a band which is continued to the anal angle. Hindwing with a pure white, compact, moderately broad submarginal band. Forewing with brilliant light blue sheen.

pyres. **E. pyres** *Godm.* is the only *Calliploea* which shows a larger white, blue- or violet-bordered subanal than subapical spot on the forewing and beneath bears postdiscal strigae on both forewing and hindwing, to which are further added the usual double row of white antemarginal and submarginal dots on both wings. Forewing above with a relatively large costal spot and the hindwing with a complete band of pronounced white submarginal patches bordered with violet. Solomon Islands, apparently rare: Bougainville, Munia, Guadalcanar

trimeni. **E. trimeni** *Fldr.* (= engrammelli *Moore*) is a small, inconspicuous species of the Northern Moluccas, of which only two races are as yet known; the name-type was described from Halmaheira and I also have it before me from Batjan, collected by Doherty in March. Somewhat like *cledonia* in shape and colouring, with a slight dark gloss on deep brown ground-colour. Forewing with five small submarginal spots bordered with whitish violet, of which two or three sometimes reappear on the upperside of the hindwing. ♀ without any reflection; the dots on the forewing more pronounced white. Under surface as above, but deeper brown, with violet tinge on the hindwing. Forewing with elongate oval discal spot. Hindwing with five strongly expressed,
duilia. rounded, violet, submarginal patches. — **duilia** *Fruhst.* is a smaller race, which Felder already knew from Obi and described together with the preceding. The steel-blue reflection covers an almost black ground, from which the submarginal dots stand out brilliantly and predominantly white. Very rare. Obi.

E. salabanda, likewise described from Halmaheira, with branch races on Obi and Batjan, extends also on to the South Moluccas. It is not impossible that it is only an extreme rainy-season form of the
salabanda. preceding, of which it bears all the characteristics. — **salabanda** *Kirsch* differs from *trimeni* in the bright, predominantly blue-black reflection on the upper surface of the wings, which mostly shows only a light
parallelis. violet subapical dot; Halmaheira. — **parallelis** *Fruhst.* is its representative on Batjan, with a row of three to five light violet submarginal spots; ♀ in contrast to that of *trimeni* with distinct steel-blue gloss above. Taken by Doherty in March 1892 together with both sexes of *trimeni*, also received by me from the month
obiana. of August from another collector. — **obiana** *Fruhst.* is a very dark form, mostly without subapical spots, but occasionally also with two to three small ones, light blue, with white centres: ♀ certainly very rare, still
cledonia. unknown. Obi. — **cledonia** *Fruhst.* (83 c) is the most distinct geographical branch: ♂ dark, ♀ light brown; ♂ with very slight steely gloss, ♀ without any. Dots on the under surface considerably more pronounced than in *salabanda* and *obiana*. Common in East Ceram; I have also before me a ♂ (bought in Paris) with the label Amboina. Earlier authors did not know the species from any of the Southern Moluccas, so that it must be very local.

E. pumila is the oldest name for a species distributed over the whole Papuan region, and affording one of the most striking examples of individual variability, being indeed one of the most variable of all butterflies. The species has consequently received a series of names, which, however, do not illustrate sufficiently its tendency to polymorphism. Even the six figures in this work do not represent all the principal types of colour-modification. Valve similar to that of *Salpinx*, strongly narrowed, with indistinctly
pumila. defined point. — **pumila** *Btlr.* (85 d) is a local form of north-western Dutch New Guinea. Ground-colour dark brown with some small whitish submarginal spots on both wings and a subapical double spot of light violet-colour on the forewing. The under surface, as in all the following races and forms, has no distal c
violet spot, which distinguishes the members of the *trimeni-mazares-hyems* group. Forewing, however, as a
lucinda. rule with a complete row of admarginal dots. — **lucinda** *Sm.* (82 e) designates a form with the upper surface of both wings predominantly smoky brown, in which the ♂♂, but especially the ♀♀, gradually shade into a violet-white in the discal area. We have figured the lightest extreme, with silky gloss all over, opalescent with whitish violet reflection. The under surface is, however, not so light, but in the basal

area and cell tinged with extremely delicate light brown. Abdomen likewise whitish violet, with brown rings. It appears that these very light ♀♀ only occur in Humboldt Bay, where Doherty discovered them in September-October 1892. — **salpingoides** *Fruhst.*, based on examples of light leather-brown ground-colour with two or three violet subapical spots on the forewing, is distinguished by a particularly light scent-patch on the hindwing, which fills up the whole of the cell and extends beyond it as an additional patch of polished appearance. The central part of this scent-patch is covered with long, dense yellow androconia. Examples with no markings at all on the upper surface and light yellow patch on the basal area of both wings have been described as **melitta** *Fruhst.* ♀♀ with still more extended light patch, which already show traces of a whitish tinge on the upper surface, I have named **sublucinda** *Fruhst.* In the neighbourhood of Friedrich-Wilhelmshafen ♀♀ commonly occur which form a transition to *lucinda* and already bear traces of a milky hyaline tinge in the cell of the forewing and between the median veins. **anaitis** *form nov.*, a rare aberration, consists of ♀♀ with small elongate-oval, opaline subapical and submarginal spots on the forewing and larger submarginal dots on the hindwing, which are accompanied by a row of admarginal dots on the underside of the latter. But by far the prettiest aberration known consists of ♂♂ with the cell and costal part of the forewing suffused with violet as in *Salpinx swierstræ* (83 c) (**amida** *form. nov.*). All the above mentioned aberrations occur in the neighbourhood of Friedrich-Wilhelmshafen in Astrolabe Bay. — In the more easterly Finschhafen on the other hand occurs a darker form, which should probably be regarded as a subspecies; this is **phokion** *Fruhst.* (83 d), which as a rule shows a deeper black-brown ground-colour, as in the figure. Most ♂♂ have supplementary violet-white submarginal spots, which are continued also on the hindwing as thin dots. All the *phokion* before me bear in addition complete rows of pure white admarginal dots on the underside of both wings. — In British New Guinea there is a local race approaching *phokion*, but of even deeper colour, — **jamesi** *Btlr.* (80 d), which in contrast to *pumila Btlr.* and *salpingoides Fruhst.* appears to be very constant, at least specimens collected in Milne Bay, in Samarai, on the coast opposite to Yule Island do not vary at all. A ♂ from Fergusson Island has also the same characteristic broad white-violet, subapical bands on the forewing as the example figured. — **flaminia** *Fruhst.* (83 c) is a larger race from the island of Salawatti with somewhat more indistinct macular bands on the forewing, but as in British New Guinea small ♂♂ occur which seem to belong to a dry-season form, have the dots small and have been described as **infantilis** *Btlr.* — **garcila** *subsp. nov.* is a local race belonging to the most westerly part of Dutch New Guinea, from Sorong, characterized by a pale brown ground-colour, dark steel-blue reflection, very small whitish submarginal patches and but little larger light violet subapical spots on the forewing. Under surface of the forewing with larger, that of the hindwing with smaller white patches than *pumila* and *jamesi*. — **stephensi** *Fldr.*, from Misol, according to the single ♀ before me is a dark brown form with reduced violet apical spots on the forewing, three submarginal patches on the hindwing, and no dots on the underside of the forewing. — **kirschi** *Moore*, of which only 1 ♀ was known until recently, represents *pumila* on Waigeu. Normal examples of both sexes closely aproach *pumila*: almost all are characterized by the submarginal spots being of equal size and the violet subapical spots somewhat larger on the forewing. Between these punctiform spots and the distal margin of the forewing a fine violet dusting is noticeable, which in many ♂♂, but particularly in the ♀♀, is sometimes broadly diffused, becomes whitish along the veins and on the under surface is visible as a grey tinge (**amantia** *form. nov.*). There is also a very rare form with unicolorous upper surface, under surface without marginal dots and the forewing only ornamented with some small streak-like dots (**parvipunctata** *form. nov.*). On the islands in the Geelvink Bay *pumila* is represented by a charming form, **sisamis** *Kirsch*, described from Ansus on Jobi and approaching *amida Fruhst.* from Kaiser-Wilhelmsland, which shows a pale violet tinge in the cell and the subapical region of the forewing and in addition is ornamented with four blue submarginal dots. Under surface as in *pumila* with some subapical dots on the forewing and a double row of white dots on the hindwing. — Finally, **bismarckiana** *Fruhst.* is the branch from the Bismarck Archipelago, characterized by the deep brown upper surface, which specially in the ♀ remains dull throughout, without the least violet or steel-blue reflection; forewing in the ♂ with violet, in the ♀ with white subapical patches, followed by some small, but distinct white submarginal spots. ♀ beneath with 2 rows of white dots on the hindwing. New Pomerania, New Lauenburg and New Mecklenburg.

salpingoides. *melitta.* *sublucinda.* *anaitis.* *amida.* *phokion.* *jamesi.* *flaminia.* *infantilis.* *garcila.* *stephensi.* *kirschi.* *amantia.* *parvipunctata.* *sisamis.* *bismarckiana.*

In the Celeban subregion, as in the Macromalayan, *Calliploea* is only represented by one species, but this is an even more brilliant one: **E. hyacinthus,** which far surpasses all the preceding species in the intensive blue reflection and is at the same time the only *Calliploea* with large white discal spot on both wings. Four local races are known as yet: **mangolina** *Fruhst.* (82 c), of which the ♂♂ only differ in the projecting inner margin of the forewing; under surface blackish with the margins of the upperside reproduced and with two instead of one submarginal row of white patches on the hindwing. Sula Mangoli. — **besinensis** *Fruhst.* most nearly approaches *mangolina* but may be at once distinguished from it by the absence of the broad white streaks in the cell of the hindwing above. It has less white dots, the large ultracellular spot in the middle of the forewing in particular being always much reduced and the patches placed before and behind it in *mangolina* appearing only as small dots or being altogether suppressed. On the hindwing the submarginal row of whitish violet dots which is always distinct in *hyacinthus* and *mangolina* is sometimes restricted to only

mangolina. *besinensis*

3 small spots, the rest of the hindwing is in one ♂ entirely without a trace of markings above, in some other ♂♂ small circumcellular hooks and patches are present. The ♀ also suggests a melanotic form of *hyacinthus* and *mangolina* and bears above only the white submarginal row of dots, a costal spot and a round median spot on the forewing, and on the hindwing only a small white helmet-shaped spot behind the cell. A second ♀ presents a somewhat brighter appearance, having two small costal spots and three circumcellular dots. The principal character, however, consists in the wholly black cell on the under suface of the hindwing, which

hyacinthus. in *mangolina* is filled up with white to one-half. Sula Besi. — **hyacinthus** *Btlr.*, in contrast to the preceding, is the lightest extreme of the species, distinguished by the yellow scent-area of the hindwing, the very broad subapical band, and by the discal spot of the forewing filling up the whole centre of the wing, particularly

subcongrua. in the ♀♀. South Celebes, not very common, ascending to about 1000 m. — **subcongrua** *Röb.* (= hewitsoni *Fldr.* 1867), judging from Felder's figure, is the somewhat less brightly coloured race of Northern Celebes, especially characterized by the blackish-dusted scent-area of the hindwing and the darker ground-colour: moreover, the cell of the hindwing beneath is grey-black to the middle instead of pure white as in *hyacinthus*. On the other hand the submarginal patches, particularly on the under surface, are more pronounced than in the southern race. Not rare at Toli-Toli, November-December, but occurring in Central Celebes (August) and distributed to the north point of the island.

b. **Subgroup Euploea** *F.* (= Macroploea *Btlr.* 1878).

Embracing the largest known species, forewing mostly pointed.

E. corus (not to be confused with *E. core Cr.*) is a Macromalayan species, which has spread westwards to Ceylon and Burma, eastwards to north Celebes and Palawan and finds its eastern limit in the southern chain on Bali. Larva cylindrical, light brown with slight purple sheen and a paler suprastigmatal region. Head and legs dark brown, the segments with brownish stripes of the same colour. Three pairs of reddish tentacles with black tips. Pupa broad, thorax uneven, silvery grey with golden brown bands, abdominal segments dorsally convex, brown-spotted. Food-plant still unknown. The statements concerning its flight are contradictory; it seems to be different in different races, either heavy and sluggish or rapid. It is only certain that all the forms are very local, exclusively inhabit the alluvial plains and even there keep near

corus. the sea-shore. — **corus** *F.* (= elisa *Btlr.*) inhabits Ceylon, where it is said to be very common at Galle among cocoanut-palm-trees. It occurs in June and July, and again in November and Dezember. I myself observed it at Colombo in 1886 and according to Nicéville it is fond of the shady jungle and on the wing may easily be mistaken for a bat. According to Moore *corus* is also met with in the mangrove swamps or else near the sea. *corus* is the smallest known race of the collective species: the spots of the upper surface

phoebus. on a light brown ground, arranged somewhat as in *vitrina Fruhst.* (79 a). — **phoebus** *Btlr.* (= castelnaui *Fldr.*) approaches *nikrion Fruhst.* (80 b), except that it has the subapical patches shorter and rounded instead of wedge-shaped and elongate, and bordered with grey-violet. Hindwing as in *nikrion*. Under surface with whitish, reduced subapical patches, but large grey-violet kernel-shaped distal spots. ♂ type from Moulmein, ♀ from Penang, also occurring in certain parts of Tenasserim, in the Mergui Archipelago and Perak, and

drucei. Singapore. An allied form was also once observed on the Nicobars. — Of **drucei** *Moore,* described from Chentabun in Siam and probably based on a dry-season form of *phoebus,* a single example only was taken by me in the temple gardens at the Menam in Bangkok in January. Forewing with somewhat reduced whitish subapical spots, hindwing with a transcellular row of violet punctiform spots, which occur also on

vitrina. the underside. — **vitrina** *Fruhst.* (79 a) is an extraordinarily local and apparently also very rare form, as neither Moore nor Bingham knew it. It is distinguished from all the allied species by the transparent pale violet anterior part of the forewing, which gradually becomes lighter from the middle of the cell on, nearly recalling *E. browni Godm.* in colouring. ♀ still paler than the figured ♂: apical part of the forewing beneath almost white, only in the cell shading into a dull yellow-brown. Lower Burma, only one pair, in coll.

hesiodus. Fruhstorfer. — **hesiodus** *subsp. nov.* is the race from Banka, where Dr. Hagen discovered it, and has still

statius. larger, lighter spots than *nikrion* (80 b). — **statius** *subsp. nov.* inhabits Sumatra, from whence it is only known to me from the north-east of the island, and differs from *phoebus Btlr.* chiefly in the darker brown-violet ground-colour, the richer violet reflection on the distal part of both wings and the more intensively violet-

phaeratena. blue-powdered subapical and more strongly expressed admarginal patches of the forewing. — **phaeratena** *Kheil* is smaller, with shorter and more rounded forewing and particularly in the ♀ almost pure white

micronesia. subapical patches on the forewing, widened into bands. Nias, apparently not very rare. — **micronesia** *Doh.* bears no white spots at all on the forewing, but only indistinct grey-violet ones, and its author was quite right when he compared this Engano race with *semicirculus Btlr.* from the far distant North Moluccas; for on account of the small dots of both wings *micronesia* has indeed much more resemblance to the Batjan race than to those of the neighbouring islands, paradoxical as it may sound. The ground-colour is a dark

pavettae. blue-violet and the ♀ is black-brown, whilst *statius* from Sumatra has light brown ♀♀. — **pavettae** *Zink.* (= gyllenhali *Luc.*) is always inferior in size to *nikrion*. Ground-colour lighter brown, with small, grey-

white patches and very restricted, insignificant blue-violet reflection on the distal area of the hindwing. *pavettae* was very rare in Java. I found the species exclusively in the neighbourhood of the sea, in the coast-forests of Palabuan, during the heaviest rainy season in January 1892. Several times a few butterflies wandered into the orchard which surrounded my dwelling-place at that time, the Pasanggrahan (rest-house) of Palabuan. They looked like ghosts, flew about two to three meters above the ground and darted and dashed so violently and irregularly through the air that for a long time it was impossible for me to recognize what butterflies I had before me. — **defiguratus** *Fruhst.*, from Bali. Dr. MARTIN's Javan collector had the good fortune to take a large series of this new *Euploea*, which I have never met with in East Java. Compared with *pavettae Zink.* from Java, *defiguratus* presents a darkened satellite-island race, distinguished by the violet instead of white proximal submarginal patches of the forewing and the much smaller antemarginal dots of both wings, which are mostly entirely absent. That *defiguratus* is also smaller than Javan examples is a matter of course in a Bali butterfly. In Lombok I had no opportunity of taking any *Macroploea*, but they are certain to be found there on the south coast in September. — **nikrion** *Fruhst.* (80 b). There are much more important differences between *pavettae* and this form from Bawean of which I have before me a series of 16 examples, collected July-September. Ground-colour darker than in *pavettae*, the violet reflection more extended and intensive, the white subapical spots of the forewing, but particularly the violet patches of the hindwing, considerably larger than in Javan specimens. — **butleri** *Moore* (♀ = godmani *Moore*) closely approximates to *nikrion*, but the forewing is more rounded; subapical spots more uniform, more sharply defined, dusted with darker blue-violet. Sandakan, Sultanat Brunei in North Borneo, Amuntai in South-East Borneo. — **salvini** *Stgr.* recalls *micronesia Doh.* from Engano in the reduced grey-violet subapical spots of the forewing, but is larger than this and shows more distinct rows of violet submarginal dots on the forewing. Palawan. Flies in January. — **grandis** *Moore*, described from a ♂ in the SEMPER collection, of unknown locality, perhaps comes from the Sulu Archipelago. Forewing longer and narrower than in *butleri Moore*, with very small discal spots. The spots of the submarginal row dentate, those of the admarginal row indistinct. Hindwing with three rows of whitish spots, of which those of the discal row are the largest. — Finally, **celebica** *Fruhst.* was described from a ♂ example from North Celebes, where I found it in the coast-forests of Toli-Toli in November 1898. Distinguished from the most nearly allied *salvini Stgr.* from Palawan by the greater expanse of the forewing and the narrower hindwing. All the dots on both sides of the wings are even more obsolete than in *salvini* and hence it is almost as unicolorous as *heurippa* from the Shortland Islands, yet not so blackish as this, but brown-coloured. Length of the forewing in the ♂ 67 mm., that of *salvini* 64 mm.

defiguratus. *nikrion.* *butleri.* *salvini.* *grandis.* *celebica.*

E. althaea approaches the figured *juvia Fruhst.* (83 a) and with its large blue spots much more recalls the Papuan *callithoë Bdv.* (79 a) than *corus F.*, from which latter, however, it differs in the positively enormous intraneural blue areas of the hindwing above and beneath. — **althaea** *Semp.* is known to me in four examples from Mindanao, where it was observed in the north at Dapitb, in the east at Taganito in May to September. — **juvia** *Fruhst.* (83 a) may be distinguished from *althaea* by the blue-violet subapical spots of the forewing being scarcely half as large and the discal patches of the hindwing likewise reduced. But in *juvia* occur further on both wings above as well as beneath a complete row of whitish, relatively large submarginal dots, which in the ♂ of *althaea* are entirely absent above, in the ♀ scarcely indicated. Taihanroku, from the 2nd to the 15th of July, 1908, collected in numbers by HANS SAUTER. An interesting discovery, as *juvia* constitutes a Philippine element in the Formosan fauna and makes it probable that *althaea* is also found on the more northerly Philippine islands. Taihanroku lies near the southern point of Formosa, so that it is quite easy to believe it may have immigrated from the Bashante or Bashi Islands of the Philippine group.

althaea. *juvia.*

E. phaenarete replaces *corus* on the Moluccas, from whence its representatives have spread over the Bismarck Archipelago to the Solomons. On some islands it is connected by transitional forms (*irma Fruhst.*, 79 b) with the Papuan *callithoë Bdv.* (79 a). — **phaenarete** *Schall.* is one of the commonest butterflies of the South Moluccas, whence it is always brought to Europe in company with *Hestia idea Cl. phaenarete* is moderately variable, both sexes being sometimes lighter, sometimes darker brown. The name-typical form is the one figured by CRAMER pl. 266, with a row of white wedge-spots in the middle of the forewing above and beneath. These spots are sometimes entirely absent (= **pauperata** *form nov.*) or there are in addition very large transcellular whitish grey or grey-violet patches of longitudinal streaks (= **luxurianta** *form nov.*). Amboina, Saparua. Ceram. — In **semicirculus** *Bthr.* (= cuvieri *Fldr.*) there begins beyond the basal colouring, which is still light brown, an area with intensive dark steel-blue sheen, in which in the ♂ are placed light blue, in the ♀ violet double rows of submarginal patches. Halmaheira, Batjan. — **hollandi** *Fruhst.* is distinguished by the more intensive blue reflection, which particularly in the ♀♀ covers the entire surface of both wings. The ♀♀ bear in addition on the forewing much larger blue-violet submarginal patches, and the underside is decorated with very large and pure white spots arranged in three rows. Buru. — **irma** *Fruhst.* (79 b) inhabits Obi. Examples somewhat smaller than *semicirculus* and *hollandi*, the blue reflection especially bright, the spots before the apex of the

phaenarete. *pauperata.* *luxurianta.* *semicirculus.* *hollandi.* *irma.*

cell on the forewing and the transcellular patches larger than in *hollandi*. ♀ very rare, approaching that of *semicirculus Btlr.* in the lighter brown basal region of the forewing. — **rolanda** *Fruhst.*, from Mangoli, one of the Sula Islands, has likewise a light brown ♀ with the light violet discal patches of the forewing more than twice as broad as in *irma* and *semicirculus* and with a double row of larger white submarginal spots also on the hindwing. ♂ dark brown with very slight distal blue reflection. Cell of the forewing surrounded with light grey-violet strigae. Under surface in both sexes with very large white intramedian wedge-spots. — **locupletior** *Fruhst.* forms a transition between brownish Macroploeas from the Sunda Islands and the brilliantly blue-iridescent species of the Papuan region and most nearly approaches in appearance *Macroploea euthoë Fldr.* from Aru. Forewing with a marginal row of pure white dots, a submarginal row of light violet, white-dotted patches, which extend nearly to the submedian. a proximal, parallel row of blue spots with but little white. On the underside of the forewing the markings of the upperside are reproduced, but are smaller and almost entirely pure white. In addition there is an ultracellular row of three white spots, of which the two intramedian ones are very large, that below the lower median vein very small. Esang, one of the Talaut Islands to the north of Celebes.

rolanda. *locupletior.*

E. unibrunnea *Godt.* is the oldest name for the unicolorous brown form of the commoner light, whitish violet **browni** *Godt.* (79 a). Between these all gradations in brown and whitish violet occur, one of which, a pretty uniformly light tobacco-brown form, has been described as *majuma Ribbe.* The ♂♂ of *browni* do not vary materially on the upper surface, beneath on the contrary the tobacco-brown colour varies in extent. The under surface of the ♂♂ bears around the cell of the hindwing more or less distinct opalescent white discal spots, which are absent in the ♀♀. — In the form **majuma** *Ribbe* these spots are sharply defined on the brown ground, and they are also present on the underside of the forewing. Pupa with golden gloss. Larva and food-plant apparently still unknown. Bismarck Archipelago, on all the islands. — **heurippa** *Godm.*, from the Solomons, I unhesitatingly refer as a local form to *unibrunnea*, and must even leave the question open whether *unibrunnea* is not also only a *phaenarete*-race. Ground-colour dark brown, dull, without reflection. Forewing with very long light brown thin streaks at the costal margin above the cell and five small, indistinct grey-violet submarginal spots, which are sometimes entirely absent. Forewing beneath with large horseshoe-shaped whitish blue spot before the apex of the cell, in place of which the representative forms bear a rounded patch. Occurs on the Shortland Islands, where it is not common. *heurippa* is fond of the dense woods and is a sluggish butterfly, which is only rarely flushed, and easy to catch.

unibrunnea. *browni.* *majuma.* *heurippa.*

E. callithoë is a purely Papuan species, which is indeed somewhat smaller than the Moluccan *phaenarete*, but is otherwise the most beautiful of the whole genus. In addition to its gorgeous colouring the collective species is distinguished by the most extensive sexual heteromorphism and to its tendency to geographical polymorphism is to be attributed the fact that it already possesses a number of names. *callithoë* reaches its highest development in Kaiser-Wilhelmsland, where two local races occur, which have hitherto been always confused. — **callithoë** *Bdv.*, the name-type, comes from northern Dutch New Guinea and probably from Geelvink Bay (Dorey). Boisduval concisely describes the form figured 79 a as follows: "Wings black-brown, with violet sheen. Forewing with a curved macular transverse band, a thick punctiform spot in the cell and two rows of pale blue marginal dots. Hindwing with some marginal dots towards the apical angle." The under surface is figured in Iris 1895, pl. IV, and shows on the forewing three transcellular white intramedian spots and on the hindwing a discal row of five small blue elongate stripes and an incomplete row of small admarginal dots. Together with it occurs not rarely at Dorey an aberration which we meet with in the entire range of distribution of the species, with two very strong glossy blue patches, which are placed isolated before the discocellular of the forewing (**biplagiata** *form. nov.*). From Sorong, the north-east cape of the main island, and from Mysol, a satellite-island, I possess six ♂♂ which bear on the hindwing beneath either no blue discal spots at all or only obsolete ones (**privata** *form. nov.*). The nomenclature of the forms from Kaiser-Wilhelmsland is very complicated, as neither Honrath nor Staudinger was aware that two faunistic regions there come together within a short distance, namely that of Astrolabe Bay with Friedrich-Wilhelmshafen, whose races in general approach those of the Dutch Humboldt Bay, and that of Finshhafen, Simbang, which with its melanotic branch-races is allied to the north-eastern part of British New Guinea. We have already become acquainted with analogous cases in *Radena juventa* and *Euploea tulliolus,* and in these giant Euploeas they are even more manifest. — **hansemanni** *Honr.*, from Simbang (Finschhafen), must be given priority as the oldest name; at the same time the ♂ is figured here for the first time (79 b) and renders a description unnecessary. The ♀ belonging to it is figured by Honrath Berl. Ent. Zeitschrift pl. V, f. 1, it resembles that of *mesocala* (79 b), except that it has a still more extended white patch, reaching the base of the forewing, and with a more blue than violet border. As far as is known the ♀♀ of the Finschhafen race do not vary so considerably as those of the local form from Astrolabe Bay. — **duerrsteini** *Stgr.*, originally described from Hatzfeldhafen, further to the west, and recognizably figured Iris 1890 pl. IV f. 2 and 3, is the form most

callithoë. *biplagiata.* *privata.* *hansemanni* *duerrsteini.*

widely distributed in collections. ♀ with much smaller light blue-violet discal spot, not distally incised, on the forewing, which in Staudinger's name-typical form bears no submarginal patches. But there occur very rarely at Friedrich-Wilhelmshafen ♂♂ with the same shaped, but considerably lighter median area of the forewing, distally united with the submarginal spots (**praestabilis** *form. nov.*). Normal ♀♀ of *duerrsteini* show *praestabilis.* a broad white submarginal area on the hindwing, of which Hagen wrote in 1897 that this whitening of the hindwing is the principal character of the Astrolabe race, the Finschhafen ♀♀ always remaining brown, which on the other hand is never the case in any variety of the Astrolabe ♀♀. It is singular that Honrath was misled in 1892 into designating as *hansimanni*-♀ *vera* a ♀ identical with *duerrsteini* on the forewing, but which has no white marginal area on the hindwing. I think this rare ♀-form, figured by Honrath (Berl. Ent. Zeitschr. 1892. pl. XV f. 6), may be introduced as **honrathi** *form. nov.* Staudinger describes as ♀-form **nera** a likewise rare *honrathi nera.* individual aberration (Iris 1895. pl. IV f. 3) with light blue cell, bordered with dark blue, on the forewing. Finally, I give the name of ♀-form **erynia** *form. nov.* to an aberration with ♂-like colouring. Forewing evenly *erynia.* dark blue with bright reflection and small light blue cell-spot, five discal strigae and six submarginal patches. Hindwing dark brown with lighter marginal area and two small median streaks. Larva of all forms according to Wahnes identical: according to a figure of Ribbe's grey-white, irrorated with black, with only two pairs of flesh-coloured tentacles on the second and third segments. The eggs produce larvae in from 5 to 8 days; but they almost immediately crawl down from the food-plant and conceal themselves. In the adult stage the larva is sluggish and lives alone, mostly hidden among the food-plant, a small tree. Pupa at first yellow, after a few days acquiring a metallical gloss, so that it looks like glass which is gilded inside. — **sacer-** *sacerdotalis.* **dotalis** *subsp. nov.* inhabits Jobi; there occur ♀♀ which are marked like the ♂ and show a large blue spot before the discocellular of the forewing, with seven to eight discal stripes, followed by distinct antemarginal patches. A ♀ in coll Oberthür has the cell of the forewing light grey-brown beneath. — **mesocala** *Voll.* *mesocala.* (79 b) is the branch inhabiting Waigeu, which, judging from the material in my collection and a few examples from coll. Oberthür which Staudinger has minutely described (Iris 1895, p. 161—164), only varies very slightly. ♂ approaching that of *callithoë*, but, as far as is known, exclusively with *biplagiata*-pattern and three long and very broad blue patches beyond and above the cell of the forewing. ♀ as figured, the white patch in the cell varying in extent, sometimes reaching to the base, sometimes only to the middle of the wing. — **eurykleia** *subsp. nov.* approaches *mesocala,* particularly in the ♀, but the blue discal spots of the hind- *eurykleia.* wing are smaller than in the Waigeu race. ♂ with broad confluent double spot before the discocellular of the forewing and very broad blue area beyond the cell. But in the cell itself the fine blue powdering, which is always present in *mesocala*, extending almost to the base, is absent. Fergusson Island. — **euthoë** *Fldr.* *euthoë.* is a distinct island form; ♂ very near that of *callithoë*, but without distinct patch before the apex of the cell and with narrower and darker blue streaks beyond the cell of the forewing than *mesocala* and *eurykleia.* Aru Islands, very rare. — On the Key Islands occurs a branch-race allied to *euthoë*, which I do not know in nature.

E. eucala *Stgr.* is a very interesting species from the Micromalayan region, hitherto only known from *eucala.* Sumbawa, but pretty certainly to be expected also from Sumba and Flores. ♂ similar to *callithoë*, but with light brown base to the forewing, thus somewhat recalling *semicirculus Btlr.* and *irma Fruhst.*, with a rounded cellular spot and a row of large, but isolated light-blue transcellular spots on the forewing. Submarginal patches, especially the upper ones, dotted with white. ♀ predominantly brown, forewing only sulfused with blue in the distal part. Forewing with three to five whitish, hindwing with seven blue discal patches: cell-dot smaller than above. A ♂ in my collection shows the anal pencils formed as in *Salpinx,* of dark yellow-brown colour, which were probably light yellow in the living insect.

Group Salpinx *Hbn.* 1816.

(Selinda, Hirdapa, Pademma, Nacamsa, Isamia, Tiruna, Anadara, Daniseppa, Satanga and *Saphara, Moore* 1883.)

Larva closely approaching that of *Trepsichrois,* with four pairs of filiform appendages. Pupa green, with metallic gloss, but the transformations of only two species (*assimilata Fldr.* from Key and *treitschkei Bdv.* from New Guinea) are known, an almost incredible fact in view of the commonness of the species. Cell of the forewing mostly without recurrent vein. Upper discocellular always distinct; cell of the hindwing relatively short. Forewing with one or two androconia-streaks, hindwing with speculum. Anal pencils with double brush of hairs, which in one species *(rhadamanthus)* is grey, otherwise bright light yellow like the stylus. The separate species are almost more inclined to sexual and local variability than even those of the preceding group and their delimitation is very difficult.

Valve very similar to that of *Crastia*, distally shaped like the beak of a bird, especially a parrot's, with the apex sometimes more rounded, sometimes sharper *(nemertes).* In *leucostictos* a pad-like swelling of the inner part of the valve is noticeable and in *ægyptus* from Bawean there is a strongly chitinized, hand-like thickening of the clasper, somewhat recalling the shape found in *Hestia.*

E. eleusina is an elegant species of *Calliploea*-like appearance. pattern of the forewing somewhat as *baweana* (83 d). but with a long. light violet sexual stripe of the forewing. by which it is chiefly distinguished
eleusina. from the very similar *E. mazares* and proved to belong to *Salpinx*. — **eleusina** *Cr.* is one of the best known butterflies of Java, where it always flies together with *mazares*, ascending like the latter to 600—800 m. above sea-level and inhabiting the same luxuriant but deserted gardens or the edges of woods. never flying far. always hovering over flowers and always easy to catch. The ♀ differs from that of *mazares* in always having a complete row of whitish violet submarginal spots on the hindwing and in three to four, sometimes much widened subapical patches on the forewing, which are placed beyond the cell. On Bawean, from July to September, *eleusina* is the commonest butterfly of the island. East Javan examples have as a rule lighter
hygina. blue submarginal markings than West Javan ones. Bali, Kangean. — **hygina** *subsp. nov.* is a butterfly not rare on Sumbawa and Lombok. distinguished by having the white submarginal spots of the forewing larger and always margined with light blue instead of violet. According to Doherty it occurs also on Sumba. —
mniszechi. **mniszechi** *Fldr.* (82 c) is a pronounced Celebes form almost entitled to specific rank. with the copious violet-white ornamentation on the upperside of both wings peculiar to all blue Celeban Euploeids. The most beautiful are the examples from the neighbourhood of the waterfall of Maros, with the ♀♀ spotted with almost pure white, white instead of blue stripe at the submedian and very large quadrate transcellular patches on
arona. the forewing. Hindwing with wedge-shaped white cell-spot and two to three discal spots (♀-form. **arona** *form. nov.*). South Celebes. Examples from the east of the island are the purest in colour and much more nearly approach the Javan *eleusina*-type than *mniszechi*. The submarginal markings are margined with dark violet instead of light blue, the submedian stripe obliterated, the discal spots of the hindwing are absent or
palata. only slight. = **palata** *subsp. nov.* Locality: neighbourhood of Tombugo.

E. vollenhovi is a species which resembles *mniszechi* and exclusively inhabits the Celeban subregion.
vollenhovi. — **vollenhovi** *Fldr.*, described from Gorontalo in North-East Celebes, differs from *mniszechi* chiefly in having a broad white transcellular band on the forewing, which in both sexes from southern Celebes is occasionally indistinct in the upper part, being dusted with blue. ♂ and ♀ like those figured, with cell-spot on both wings and broad pure white median area (which on the figure has by mistake been covered over with blue),
anitra. occur only in Central Celebes in August-September, = **anitra** *subsp. nov.* (83 c). They are also beneath easy to distinguish from other Celeban *vollenhovi* by the very large white wedge-spots before the apex of the cell
aganor. on both wings. — **aganor** *subsp. nov.* is a satellite-island form with strongly reduced sexual spot and small transcellular patches on the forewing. Hindwing in the ♂ without cell-patch and only with two discal patches; ♀ with very small spot before the discocellular. Bangkai.

E. dehaani likewise resembles *Calliploea* in habitus; it somewhat approaches *ledereri Fldr.* from Malacca in size, but differs from this in the absence of the lighter brown patch at the hindmargin of both wings and the presence of the *Salpinx*-spot on the forewing. Moreover, the submarginal row of spots is distinctly dotted
dehaani. with white, reaches to the submedian and consists of larger, more wedge-shaped patches. — **dehaani** *Luc.*, described from Cochinchina, was found by me in southern Annam; the discal row of blue spots and particularly
musa. also the rounded patch before the apex of the cell on the forewing smaller than in **musa** *Swinh.* (= miraculosa *Fruhst.*), which must be regarded as a characteristic butterfly of Tonkin, where it is nowhere rare from June to September at elevations of 300—600 m. above the sea even in the neighbourhood of human habitations.
minorata. — **minorata** *Moore* (= hainana *Holl.*), unknown to me in nature, was described from Hainan, the fauna of which shows such a surprising resemblance to that of Tonkin. According to Holland's description, *minorata* differs from *ledereri,* as figured by Felder and Distant, in that the row of submarginal spots of the forewing consists of seven instead of six spots and that all these patches are indistinctly dotted with white. The chestnut-brown tinge, so characteristic of *ledereri,* is wanting both at the hindmargin of the forewing and on the hindwing. Under surface as in *ledereri.*

E. leucostictos is one of the commonest Euploeas throughout its wide range, which extends from Formosa in the north, across Further India southwards to the Nicobars, and to the east embraces the Mariannes. It is, however, essentially a Macromalayan species, dominant everywhere on the large Sunda Islands and their
hobsoni. satellites together with *Trepsichrois mulciber.* — **hobsoni** *Btlr.* is not very common on Formosa, at the extreme limit of the range of the collective species, and approaches *coelestis Fruhst.* (83 b), but is somewhat smaller, the submarginal patches are lighter blue and the subapical stripes on the forewing of the ♀♀ distinctly dotted with white. All the blue spots. moreover, extraordinarily broad, as is already mentioned by Butler who had only one ♂ for description. There are two forms, the normal, and a rarer one with extended, elongate-pointed
gaza. subcostal strigae, especially in the ♀ (= **gaza** *form. nov.*). Locality: Taihanroku, near the southern point of
negleyana. the island, July-August. — **negleyana** *Holl.* is about intermediate between *hobsoni* from Formosa and *coelestis*

from Tonkin; according to its author it is not rare on Hainan and bears, judging from the figure, distinct whitish antemarginal dots on the forewing and essentially smaller blue submarginal patches than *hobsoni* and *coelestis*. Not known to me. — **leucogonys** *Btlr.*, originally described from Malacca, extends northwards to Moulmein and was met with by me in February in Central Siam and in March at the border of Siam and Burma. In general they visit flowers, but in the dry season are fond of wet places in the waterless river-beds. *leucogonys* varies much in size, some ♂♂ only betray their relationship by two or three light blue transcellular patches; the submarginal patches may be either small or very large (= **lazulina** *Moore*). As localities are further known: Salanga, Singapore. — **vestigiata** *Btlr.* is a race with the hindwing generally darker, without discal stripes and as a rule with small or only moderate-sized submarginal patches on the forewing. As in the preceding form ♀♀ sometimes occur with pure white or slightly light violet anal margin to the hindwing, which, however, is not reproduced on the under surface (**albolimbata** *form. nov.*). Valve distally less excurved than that of *viola* from Celebes. Rare in North-East Sumatra. *vestigiata* is one of the commonest butterflies in the west of the island and the ♀♀ attain there an unusual size, but nevertheless have generally only a smaller stripe at the submedian of the forewing than *leucogonys*. According to Martin they are fond of shade and hence sometimes come under bridges covered with wood or straw, and even into the verandas of dwelling-houses, where they remain until about 4 o'clock, and then return to their hiding-places in the woods. — **novarae** *Fldr.* is a race from the Nicobars rare in collections, and only known to me from Moore's figure; forewing with light blue submarginal spots on dark blue, brilliantly glossy ground. — **juno** *Stich.* is a race approaching *vestigiata* in the predominantly dark blue-violet ground-colour of the upper surface, the ♀♀ of which, however, may be distinguished from the West Sumatran branch of the species by the very large subapical patches with pure white dots and the light blue, similar submarginal spots. Under surface of both wings with very distinct, complete rows of pure white submarginal dots. Rather rare. Nias. — **phane** *Doh.* on the contrary is very common (coll. Fruhstorfer contains 63 examples, captured in April). Ground-colour steel-blue, never changing into violet and hence easy to distinguish from *juno* and *vestigiata* and probably at the same time approaching *novarae Fldr.* from the Nicobars. *phane* also differs in the dark hindwing both from *leucostictos Gmel.* from Java and *vestigiata Btlr.* from Sumatra, both of which have the hindwing much lighter distally. ♂, but especially the ♀, with very large marginal spots, as a rule light blue, only rarely dotted with white. The *Salpinx*-spot in both sexes very large, in the ♀♀ often distally incised, sometimes double or so much widened as to recall *kulu* from the Philippines. But the principal character of the race consists in the almost undotted under surface (forming a contrast especially to that of *juno*), which in the ♂♂ is almost deep black and suffused with dark blue sheen. Engano. — **leucostictos** *Gmel.* (= eunice *Godt.*), the name-type, is one of the most variable races, with the ground-colour as a rule light brown with violet tinge. Examples with dark steel-blue reflection are rarer. The shape and colour of the submarginal patches vary, but examples predominate with light violet marginal patches, more or less dotted with white. The *Salpinx*-stripe is as a rule smaller than in *phane* and in the ♀♀ inclined to obsolescence. In single ♀♀ it is entirely absent (= **debarbata** *form. nov.*). In some ♂♂ appears as a rare exception a second rounded violet spot above the *Salpinx*-stripe (**bioculata** *form. nov.*), a series of ♂♂ and ♀♀ bear transcellular elongate or rounded strigae on the forewing (**radiata** *form. nov.*), whilst other examples, especially often ♀♀, show occasionally only four small, white-centred subapical spots, which only extend to the upper median vein of the forewing (**abrupta** *form. nov.*). In East and West Java nowhere rare up to 600 m.: but it is always met with singly, never gregariously, like *mazares*. — **timaius** *subsp. nov.* is a very large and dark-coloured race with light blue submarginal patches, but never light violet according to the material before me. ♀ as in that of *juno* with elongate subapical strigae, which distally enclose large white dots. Under surface darker and with smaller dots than in Javan examples. Bawean, apparently rare. — **relucida** *subsp. nov.* is a race with brown ground-colour, closely approximating to *leucostictos* from Java in the colouring of the upperside: ♂ with light violet. ♀ with light blue subapical and submarginal patches. The under surface forms a distinct transition to *tisais Fruhst.* from Lombok in the strikingly light coffee-brown patch in the cell of the forewing and the median area of the hindwing. Bali. — **tisais** *Fruhst.* (83b), described from Lombok, where it is fond of visiting flowers at elevations of 2000 ft. and was met with by me as one of the first butterflies immediately after sunrise. The upper surface is shown in the figure, the under surface is characterized by delicate light blue submarginal spots, and light brown patches in the cell of both wings, which gradually shade off into the somewhat darker marginal area. — **kandaon** *subsp. nov.* bears as a rule even larger and lighter blue submarginal spots on the forewing and is beneath easy to distinguish from *tisais* by the sharply defined dark brown marginal area, distinctly shot with violet-blue, on both wings. The white dots of the under surface are commonly replaced by small black dots with scarcely appreciable blue centres. Sumbawa. — **meizon** *Doh.* is an extremely pronounced geographical form, somewhat inferior in size to *kandaon*, but nevertheless with the marginal spots of the forewing almost larger and always light blue. The under surface similar to that of *phane*, i. e. much darkened, with a slightly lighter brown area in the median part, and both wings either entirely without dots or only with a few small blue spots in the subapical part of both wings. Sumba. — **syra** *Fruhst.* (79c), from Borneo and Palawan, is an exceptionally large form with dark velvety blue ground-colour and as a rule only three to five subapical patches on the forewing. The *Salpinx*-

leucogonys. *lazulina.* *vestigiata.* *albolimbata.* *novarae.* *juno.* *phane.* *leucostictos.* *debarbata.* *bioculata.* *radiata.* *abrupta.* *timaius.* *relucida.* *tisais.* *kandaon.* *meizon.* *syra.*

spot is always larger than in the allied forms, commonly as in the figure, but sometimes, especially in the ♀♀, three to four times as broad and slightly dotted with white. Sometimes there is also in the ♀♀ a second spot between the median veins and the hindwing is further adorned with two to three quadrate discal patches
kadina. beyond the cell-wall (**kadina** *form. nov.*). Occurring in all parts of Borneo, but everywhere rare. Flies on
oculata. Palawan in January. — **oculata** *Moore*, originally assigned only to a small dry-season example from Mindanao. must be adopted as the only valid name for the probably rather similar representatives of *leucostictos* from the Philippines. According to Semper specimens with large and small spots occur at the same time and in the same place, yet examples are not known from the Philippines with the submedian stripes as strongly
kadu. reduced as in *syra*. Apparently rather rare, from Luzon to Mindanao. — Finally, **kadu** *Ersch.*, first described from Guam in the Mariannes, is somewhat smaller than normal Mindanao specimens, but bears by far the
hewitsoni. largest grey-white *Saluinx*-spots on the upperside of the forewing. **hewitsoni** *Btlr.* is only a form of *kadu* with two submedian stripes on the forewing. According to Matsumura (Stutt. Ent. Zeitschr. Aug. 1909, p. 91) *kadu* has also been taken on Formosa and even on the Loo-Choo Islands.

E. viola replaces *leucostictos* and its representatives on Celebes and is actually also connected with it by transitional forms. But as in the ♀♀ (83a) the *Salpinx*-spot at the submedian of the forewing is absent and the genitalia also differ. this purely Celeban butterfly is treated as a distinct and separate species. Valve distally essentially broader than that of *vestigiata Btlr.* from Sumatra, ventrally with sharper and distinctly defined point. Celebes itself produces two sharply separated local races, although strange to say the differ-
viola. ences between them have not been noticed hitherto. — **viola** *Btlr.* (83b), the well-known form from Northern Celebes. which flies there all the year round and is never missing in consignments from the Minahassa; ♀ with withish. broad, light violet-bordered submarginal spots and a slightly curved row of subapical. transcellular stripes on the forewing. which never bears discal white spots. Hindwing above with cordiform, violet-dusted submarginal and white admarginal patches. Under surface of ♂ and ♀ without a trace of cellular or discal patches, hindwing moreover only with very minute dots, which traverse the submarginal area in two
weberi. rows. ♀ sometimes with a lighter, grey-violet-powdered postdiscal area on the hindwing. **weberi** *Moore* is
brandti. an aberration with small white submarginal spots on the hindwing, and **brandti** *Moore* an interesting form with medium-sized discal spots, but no submarginal patches on the forewing. Both probably from North Celebes, types in coll. Distant. An aberration in coll. Fruhstorfer, nearly allied to *weberi,* with obsolete
upis. submarginal spots and diffuse subapical patches on the forewing, is here introduced as **upis** *form nov.* —
westwoodi. **westwoodi** *Fldr.* (83a ♀) exclusively inhabits Southern Celebes and is at once distinguishable from *viola*, particularly beneath. by a discal row of spots, already figured by Felder, which in the ♂ are light blue and only of medium size, in the ♀ pure white, sometimes even forming quadrate areas. The forewing bears in both sexes extremely pronounced subapical, transcellular white spots, and the submarginal patches of the hindwing are always more prominent than in the northern form. Above the blue discal spots of the ♂ are always more strongly expressed, and sometimes assume a pure white colour, as may be seen from the figure
perizonia. (**perizonia** *form. nov.*. 80a ♂) and are confluent with the light blue marginal spots. ♀ always with purer white intraneural bands of the forewing than in *viola*, only sparsely bordered with violet. Two melanotic aberrations deserve mention: ♀ with only one row of medium-sized submarginal spots and a central patch. but without transcellular stripes on the forewing, hindwing with large, wedge-shaped, grey-violet-powdered postdiscal areas. Under surface of both wings with three rows of white punctiform spots
aisa. but not clouded with whitish violet (♀-f. **aisa** *form. nov.*). ♀ above as dark brown as the preceding, but with circumcellular stripes on the forewing. Hindwing also above with three rows of white patches and beneath
nivira. with broadly diffuse white, violet-powdered intraneural areas (♀-f. **nivira** *form. nov.*). In Southern Celebes,
bangkaiensis. especially in the dry season on flowering trees, which sometimes appear as if covered with them. — **bangkaiensis** *Fruhst.* agrees in size with Celeban *viola,* but bears much smaller whitish violet spots on the forewing and only one row of submarginal dots. From this branches off beyond the cell-wall towards the costal margin a curved row of four subapical spots. On the hindwing above the violet macular band which adorns *viola* is entirely absent. Beneath two submarginal rows of small white dots likewise recall *leucostictos,* whilst *viola* is ornamented with deep blue and larger dots. Type in the museum at Dresden. *bankaiensis* forms a connecting link between *leucostictos* from the Sunda Islands and the copiously blue-spotted *Salpinx viola.* —
leochares. **leochares** *subsp. nov.* is a darker race discovered on Salayer by Dr. Martin, with the white submarginal bands on both wings much reduced. In colouring it somewhat approaches *labreyi Moore.*

meyeri. **E. meyeri** *Hpffr.,* of which as yet only the type-specimens, in the Berlin Museum, have been brought to Europe, nearly approches.

depuiseti. **E. depuiseti** *Oberth.,* which is perhaps even a local form of the preceding and must be regarded as one of the finest Euploeids. Both sexes with a double spot of peculiar green-grey-blue colour at the submedian of the forewing, above it in the ♀ also another larger round white patch.

Transcellular spots and the proximal part of the subapical wedge-shaped streaks of the forewing likewise dusted with grey-green. Hindwing with a proximal row of very large white submarginal patches, of which the upper ones are also margined with blue-green, and a complete series of very distinct admarginal dots. Under surface somewhat as in *martini* but with a further row of greenish-dusted discal patches on the forewing. Sangir. — **lykeia** *subsp. nov.* is a geographical form from the Talaut Islands with reduced white and grey-blue patches on beth wings. *lykeia.*

E. labreyi *Moore* (= plateni *Stgr.*) (80 a) is the last of the representatives of *viola* and *leucostictos* and comes from Sula Mangoli, where Doherty rediscovered it. The ♀ differs from the ♂ in the presence of large white submarginal patches on the hindwing. As in *viola* the *Salpinx*-spot is wanting on the upperside of the forewing. *labreyi.*

E. nemertes was formerly regarded as a local race of *leucostictos,* which it indeed replaces on the Moluccas and in the Papuan region in its widest extent. but from which it is specifically sharply separated. apart from the differences in the markings and the absence of the blue reflection on the upperside of both wings, by the entirely different shape of the genitalia. Valve narrow, approaching that of *Stictoploea,* distally not shaped like a parrot's but rather a mouse's head. Apex strongly chitinized. obtuse. ventrally curved inwards. — **nemertes** *Hbn.* (= aglidice *Bdv.* ♀, pasithea *Fldr.*) is the commonest *Euploea* of the South Moluccas and distributed in collections from Amboina and Saparœa. Moderately variable: it varies as a rule only in the size of the light violet *Salpinx*-spot in ♂ and ♀ and the extent of the white subapical patches. which in specimens especially copiously decorated with white show a fine violet-grey distal powdering. In some ♀♀ there is also a complete row of whitish submarginal dots on the hindwing above. In the ♂♂ violet discal stripes sometimes occur on the underside of the forewing, which are always distinctly expressed in the ♀. — **hisme** *Bdv.* (84 a) differs from *nemertes* only in the darker brown ground-colour. a slight violet sheen on the upperside of both wings and on the forewing a more complete row of smaller submarginal dots with darker blue margins. On the under surface of the forewing the white dots are more pronounced than in *nemertes.* Buru. — **lycoleon** *subsp. nov.* is a light brown form from eastern Ceram with only four small white subapical patches on the forewing, the underside of the hindwing margined with light brown and extremely delicate, pale violet discal streak on both wings. — **bernsteini** *Fldr.,* described from Halmaheira and the Aru Islands (the latter locality is incorrect), inhabits the North Moluccas and is to be met with on Batjan all the year round. Subapical spots on the upperside of the forewing absent. ♀ as a rule only with 2—3 small subapical spots on the hindwing beneath. the ♂ on the forewing without a trace of discal streaks. the ♀ with these only slightly indicated. Both sexes only with one submarginal row of violet dots on the hindwing. — A dry-season form of somevhat lighter colouring, with the *Salpinx*-spot on the forewing much reduced, passes in the trade as **hismina** *form. nov.* — **pseudohisme** *subsp. nov.* is a darkened race from Obi. chiefly characterized by the ♀♀, which beneath show very large. rounded, white submarginal patches. Moreover. the discal spots on the forewing beneath are enlarged. **trysa** *form. nov.* is a ♀-form without blue-violet spot at the submedian of the hindwing. thus forming a connecting-link with the purely Papuan local races, in whose ♀♀ the submedian spot is always absent. — **staintoni** *Fldr.* (80 c). a very distinct geographical race, which already exhibits to a great extent the tendency to polymorphism so characteristic of the Papuan region: only in sexual heteromorphism the races of the main island of New Guinea surpass *staintoni.* Besides the typical form figured there are four directions of variation to be described: **eretria** *form. nov.,* similar to *erima* (85 a) and *gorima* (83 c), unicolorous brown with the distal part of both wings somewhat paler. **punctaria** *form. nov.,* similar to *quintia* (81 a), brown, with six strong white rounded patches on the forewing, which in the ♀♀ are distally margined by an especially light border. sometimes inclining to violet. **hortensia** *form. nov.,* with broad violet marginal area on the forewing. which is especially prominent in the ♀, sometimes becomes entirely white towards the apex and may even extend over the whole forewing as in the ♀ figured. **impressa** *form. nov.* is the rarest aberration, and may be combined with *hortensia* pattern: it is ornamented with small brown submarginal spots. which look as if sprinkled or printed on to the wings. Waigeu. described from 60 examples in coll. Fruhstorfer. — **herbsti** *Bdv.* is the subspecies which inhabits the whole of Dutch New Guinea and the islands of Geelvink Bay (Salawatti. Misol. Jobi. Biak), and of which Grose-Smith has given the name **traducta** to light brown examples. such as I have before me from Sorong. with a slightly bronzy sheen above. Quite small examples without a trace of subapical blue or violet patches are called **minima** *Gr.-Sm.,* and a very interesting aberration with violet tinge near the apex of the cell on the forewing is **swierstrae** *Snell.* (83 c). Boisduval himself knew only a form analogous to *quintia* (81 a), which bears on the forewing six pale violet, medium-sized submarginal patches on a light brown ground. — The oldest name for the geographical branch from Kaiser-Wilhelmsland is **erima** *Fruhst.* (85 a), which was first applied to the dominant form from Astrolabe Bay. of more uniform yellow-brown colour throughout than examples from Dutch New Guinea. A very common aberration with pale yellow-brown ground-colour, which occurs at Friedrich-Wilhelmshafen on the coast up to many thousands in company with *Calliploea salpingoides,* I designate **gorima** *form. nov.* (83 c). Examples with thin light violet shading before and behind the discocellular of the forewing. which form a transition to *swierstrae*

nemertes. *hisme.* *lycoleon.* *bernsteini.* *hismina.* *pseudohisme* *trysa.* *staintoni.* *eretria.* *punctaria.* *hortensia.* *impressa.* *herbsti.* *traducta.* *minima.* *swierstrae.* *erima.* *gorima.*

and are not very rare in both sexes. are **atomaria** *form. nov.* Very rare on the other hand is a form analogous to *Euploea pumila* f. *lucinda Sm.,* with opalescent white colouring. which only betrays its identity with *erima* by the narrow, diffuse, brown margins (**opalina** *form. nov.*) (85 b as *swierstrae*-♀). **sexguttata** *Fruhst.* is the name of a ♂-aberration. with six light violet patches on a light brown ground. In the ♀♀ the patches are pure white with fine light blue borders. *swierstrae Snell.* occurs both at Friedrich-Wilhelmshafen on the main island and on Vulcan Island. — At Finschhafen occurs a completely modified race, already approaching that of British New Guinea in the dark, almost black-brown ground-colour. two very large white subapical patches bordered with light violet and four diffuse submarginal spots on the forewing. Under surface likewise very dark, sometimes with 2 rows of large white subapical spots on the forewing. = **aviena** *subsp. nov.* Thus the condition of *Salpinx* in German New Guinea almost agrees with the statements of Prof. Neuhauss, who asserted that the fauna changes there with every kilometer. The valve of *erima* differs from that of *nemertes* in the slenderer form. the narrower and more abruptly narrowed tip. — **quintia** *subsp. nov.* (81 a). Wings darker throughout, almost black, with rich blue-violet tinge. Examples predominate with unusually large white apical and submarginal patches. which in the ♀ are strongly expressed on the hindwing also, but are never so extended as in *erima* and *herbsti.* Together with the typical form. however, there occur on the mainland, and rarely on Fergusson Island, a large proportion of ♂♂ and ♀♀ with no patches at all on the forewing (**rhodia** *form. nov.*); Milne Bay and Aroa River. in British New Guinea. Trobriand and D'Entrecasteaux Islands. — **messia** *subsp. nov.,* similar to *rhodia,* only smaller. but above with much larger milk-white discal spots on the forewing. Woodlark Island. — **oppia** *subsp. nov.* is noticeable for its dull earth-coloured ground-colouring, the lighter, almost grey-brown distal part of both wings and the complete submarginal row of violet dots on the hindwing beneath, which stand out more conspicuously than in the other Papuan races of *nemertes.* Mefor. — **perdita** *Btlr.* approaches *quintia* and *rhodia* and is distinguished by the uniformly dark brown colouring and distinct white submarginal patches on the underside of both wings. The upper surface, on the other hand, is very delicately dotted with white. — **ulaguna** *Ribbe* is a form in which the *Salpinx*-spot at the submedian of the forewing is obsolescent. whilst the hindwing is characterized by a row of more pronounced submarginal and very small admarginal dots. Bismarck Archipelago. everywhere common. — **polymela** *Godm.,* the largest of the eastern forms. above somewhat lighter brown than *perdita,* without marginal dots, but with large oval pale violet sexual spot. The ground-colour varies occasionally from light to darker, the ♀♀ bear above white submarginal patches, which according to Ribbe are sometimes continued on the forewing; nowhere rare in the Solomons. — **iphianassa** *Btlr.* (— consanguinea *Btlr.*). described from Aneitum in the New Hebrides, is characterized, according to the ♀♀ before me. by white, fairly uniform submarginal patches about the size of a pin's head, which are continued on the hindwing to the middle of the wing, and are reproduced on the under surface, so that the hindwing also is adorned with submarginal patches to the anal angle. — **graeffiana** *H.-Schäff.,* from Vate in the New Hebrides. is easy to distinguish from the preceding by a light distal border on both wings. — **macleayi** *Fldr.* again closely approximates to *iphianassa,* except that it bears somewhat smaller. but complete and purer white rows of dots on the upperside of both wings. Fiji Island. apparently rare.

atomaria. *opalina.* *sexguttata.* *aviena.* *quintia.* *rhodia.* *messia.* *oppia.* *perdita.* *ulaguna.* *polymela.* *iphianassa.* *graeffiana.* *macleayi.*

E. asyllus *Godm.* is a very distinct species, being an interesting parallel form to *E. pyres Godm.,* and like this easy to distinguish from its allies in the Solomon Archipelago and New Guinea by strongly expressed discal rows of blue-white spots, which traverse both wings in addition to the two submarginal rows. ♂ above scarcely differing from that of *polymela,* ♀, however, with whitish subapical and transcellular spots, which vary in size. Bougainville, Rubiana. — **laurentia** *subsp. nov.* is a distinct race. ♀ above darker brown, but on the hindwing with distincly defined pale yellow-brown marginal area. Forewing, except for a costal patch, entirely without spots. The submarginal dots of the forewing only extend to the middle of the wing. Shortlands Islands, discovered by C. Ribbe.

asyllus. *laurentia.*

E. usipetes is the same shape as *nemertes, herbsti* and *staintoni,* so that one is tempted to regard it as the *nemertes*-form from Aru. and where it occurs in British and German New Guinea together with *quintia* and *gorima,* as one of the many aberrations of those *nemertes* branch-races. But as the valve shows some difference *usipetes* is here treated as a species and only a knowledge of the larva can decide conclusively as to its validity or otherwise. Valve somewhat broader, but nevertheless more pointed than in *nemertes, erima* and *fraterna.* — **usipetes** *Hew.* (85 c ♀) is known from the Aru Islands, where it occurs together with *assimilata Fldr.,* which likewise cannot be united with *usipetes* as a form on account of the narrow valve, this being much broader in *assimilata* than in *nemertes.* Together with ♀♀ like the one figured, some also occur according to Ribbe with white instead of brown-yellow disc (**albodiscalis** *form nov.*). — On the main island of New Guinea, both in the British and German part, occurs a specially handsome race: **astrifera** *subsp. nov.* (85 c as *usipetes*-♂), with six to seven prominent pure white, blue- or violet-bordered submarginal spots on the forewing. which are also present in the ♀♀. The discal colouring varies from that of *albodiscalis* to dull yellow-brown. ♂♂ of the darker colour have usually only two to four small obscure grey-white subapical spots. — **rezia** *Kirby* is a further geographical form. ♂ with the disc of the forewing very slightly

usipetes. *albodiscalis.* *astrifera* *rezia.*

lighter, but ♀ with violet-white extended median area. Fergusson, Kiriwana. — **hippias** *Misk.,* from Cape York, is only known to me from its author's description. Upper surface rust-brown with pale brown disc, which becomes yellowish white distally. Hindwing with a very large oval ochre-brown cell-spot, which distally somewhat approaches the costal margin. *hippias.*

E. imitata *Btlr.,* without more exact locality, was discovered on the cruise of the "Curaçao", according to Butler from the Solomons. *imitata.*

E. assimilata is a species which occurs exclusively on the Key Islands and some of the small south-easterly Moluccas. It is noticeable at once for an extended light patch, particularly beneath, which finds its analogy in *eurypon Hew.,* as well as in *Calliploea hopfferi Fldr.* from the same groups of islands. Valve approaching that of *erima Fruhst.,* from New Guinea, but somewhat longer, uniformly narrower. — **bandaënsis** *Fruhst.* (85 b) is not rare on Banda, where it occurs in two principal forms: the dark ♀-f. *bandaënsis,* which has but little light scaling above, with the white submarginal spots of the hindwing distinctly showing through from the underside, which are placed in a pale brown area, inclining to whitish, particularly beneath; and **nepotina** *Fruhst.* (85 b) with broad and pure white marginal area on the hindwing in both sexes. *nepotina* always bears beneath only three large, tear-shaped transcellular patches instead of a complete row of submarginal dots. — **nepos** *Röb.,* from Goram, shows a still more sharply defined and broader white distal border on the hindwing and whitish-scaled apical part of the forewing. I have before me only one ♂ with three relatively small discal patches on the hindwing beneath. — **assimilata** *Fldr.* (♀ = fraterna *Fldr.*) is the albinotic extreme of the collective species. Forewing with the white submarginal bands as broad as *nepotina* shows them on the hindwing only. Under surface of the hindwing with large white tear-spots. Felder erroneously described the form from Aru, where according to Ribbe it does not occur and has no representative. Kühn has discovered the larva on Key; it is of black ground-colour, each segment with several thin yellowish stripes. Head, abdomen and legs entirely black. The four pairs of tentacles reddish with black tips. Pupa metallic green. — **frigida** *Btlr.* is according to the description allied to *bandaënsis;* it is said to come from North Ceram. *bandaënsis. nepotina. nepos. assimilata. frigida.*

E. treitschkei inhabits the Papuan region, extends eastwards to the Solomons and even to the Fiji Islands, but does not seem to reach westwards beyond the neighbourhood of Geelvink Bay, being absent even in Waigeu. On the main island of New Guinea the butterfly is probably of pretty general occurrence; sexual dimorphism not known from there; like *E. nemertes* and *Calliploea pumila,* however, the species is inclined to local variation, even Vulcan Island, only 10—12 km. from New Guinea, has a highly specialized branch race. Wahnes has discoverred the larva; according to a figure for which we are indebted to C. Ribbe, the ground-colour is yellow-brown, with black lateral stripe, head black, four pairs of filiform appendages yellowish. Pupa as in other species metallic golden. Larva lives in numbers, but not gregariously, on a creeping-plant which covers the sandy sea-shore. — **olivacea** *Sm.* (81 b) occurs in the whole of Dutch and German New Guinea and varies slightly in that the ♂♂ sometimes bear above no white or greenish grey stripes at all, nor any cell-patches (= **unicolor** *Hag.*); there are all transitions to the form figured with 5 discal splashes, to which are sometimes added one or two white subapical patches on the forewing. In the ♀, which is lighter than the ♂, with metallic green-yellow reflection, similar variations are repeated, only there occur, especially at Finschhafen, examples with whitish powdering in the apical part of the cell of the forewing and only whitish intramedian diffuse stripes (= f. **pulverulenta** *form. nov.*). Flies according to Hagen from September to December, and again in April. — **aebutia** *subsp. nov.* is a darger race from Jobi. Ground-colour green instead of black, with steely blue gloss, ♀ but little lighter, the discal patches blue-white. Under surface extremely sparsely dotted. ♂ above without *Salpinx*-stripe. — **eugenia** *subsp. nov.* (84 a) is the albinotic extreme of the preceding. Wings light sea-green with white subapical patches of the size of lentils on the forewing and circumcellular spots of the same colour on the hindwing. Cell of the forewing with *pulverulenta*-pattern, which is absent beneath. Vulcan Island, discovered by Dr. Eugen Werner. — **ursula** *Btlr.* (80 b) differs from *eugenia* chiefly in that the anal postdiscal white spots are more extended, but the cell of the hindwing encloses no white dot before the apex, which, however, is again present beneath. Fergusson. — In ♂♂ from Kiriwina all the white intramedian stripes of the hindwing are wanting, so that we have before us an unmarked form analogous to *unicolor Hag.,* which probably approaches **viridis** *Btlr.*, unknown to me in nature and described from a ♀ from Thursday Island. — **decia** *subsp. nov.* is a form from Milne Bay in the British territory, with white intraneural splashes on the hindwing arranged as in *ursula,* but smaller. — **treitschkei** *Bdv.*, the name-type, described from New Mecklenburg, is somewhat smaller than *olivacea*-♀, on the forewing with *pulverulenta*-pattern, hindwing with large, sharply defined, pure white circumcellular patches. **erimas** *Godt.* (= albopunctata *Ribbe*) is a handsome aberration with extended light patch on the forewing, which sometimes shows a very large white median area. — **biformis** *Btlr.* sometimes darker and predominantly blue-green, with somewhat smaller white dots than the type-form from New Mecklenburg. Described from Duke of York Island (New Lauenburg). — **coerulescens** *Pag.*, which I have not before me, differs in having a very conspicuous blue gloss in both sexes and more numerous white spots on the upper surface. ♀ usually *olivacea. unicolor. pulverulenta aebutia. eugenia. ursula. viridis. decia. treitschkei. erimas. biformis. coerulescens.*

lorenzo. with *pulverulenta*-pattern and on an average somewhat larger than *treitschkei*. New Pomerania. — **lorenzo** *Btlr.* was described from the Solomons without more exact locality, unknown to me. Probably it approaches *salomonis Ribbe* from the Shortland Islands; above like *unicolor Hag.*, but with larger *Salpinx*-stripe on the *aenea.* forewing. Discal dots on the under surface reduced. — **aenea** *Btlr.*, likewise inaccessible to me, erected on *jessica.* a ♀ from the Solomons. — **jessica** *Btlr.* is said to come from the Fiji Islands, a locality which I much question, as the species has never again been brought to Europe from thence. According to the figure it is allied to *ursula*, but bears yellowish instead of grey-green discal spots on the forewing, and very broad, elongate spindle-shaped sexual stripe. Hindwing with broad submarginal band, composed of larger patches than in *ursula*, placed in pairs. According to the markings *jessica* probably comes from the satellite-islands of eastern New Guinea.

gamelia. **E. gamelia** *Hbn.* (= faber *Zinck.*) recalls *eichhorni Stgr.* (81 c) in its refined general colouring, except that in *gamelia* the luxuriant white is extended on to the forewing. On a deep velvety black ground are placed three long oval, pure white transcellular spots, to which are added above the cell three costal patches and an irregular series of admarginal dots, following the same course as in *martini* (80 c). The double row of white marginal dots on the hindwing is widely separated, not confluent as in *martini*. In the glossy blue scent-area of the hindwing above a pointed oblong grey-yellow androconia-patch. Found by me exclusively in West Java, and there only at the volcano Gedé and at elevations of not less than 4000 ft.

martini. **E. martini** Nicév. (80 c) considerably surpasses *gamelia* in size; ♀ about as common as the ♂, differing in the duller brown ground-colour and broader submarginal spots in both wings. ♂ without oblong androconia-patch on the scent-area of the hindwing. Forewing prominent among all the *Salpinx* by possessing two long, narrow sexual streaks, which to a certain extent bring it near *Stictoploea* and which in *gamelia* are replaced by a short, more rectangular scent-spot. Sumatra, not below 1000 m.; not rare, but also not one of the commonest butterflies of the district.

roepstorffi. **E. roepstorffi** *Moore* rather ressembles *aelia* (85 c), except that the submarginal patches of the hindwing are more than twice as large and the forewing adorned with two discal and four subapical spots, sometimes rounded and sometimes elongate. Very rare, only one example yet known, which was in coll. Semper, and is now in the possession of Herr Weiss of Deidesheim. Andaman Is.

E. aegyptus, a Macromalayan species which is split up into sharply differentiated branches on the separate islands. In common with *martini* a second, although smaller sexual stripe is occasionally present on the forewing. It is not impossible that the name *ochsenheimeri Luc.* (1853) is entitled to priority. Absolute certainty could only be arrived at by examination of the type, which is said to be in the Paris Museum, but as the name clashes with *ochsenheimeri Moore* it would only tend to cause confusion and is hence provisionally *aegyptus.* suppressed. — **aegyptus** *Btlr.*, the type of which probably came from South Borneo or Sarawak, differs from the figured *rafflesi* (84 a) in the more pronounced white spots of the forewing. Valve similar to that of *E. leucostictos, vestigiata Btlr.*, but more quadrate, distally cut off straighter, the obtuse tip somewhat separated *lowei.* from the main part by a distal incision. **lowei** *Moore* is an unimportant aberration with somewhat larger white apical spots and without marginal dots on the forewing. Hindwing likewise with reduced rows of dots. *singapura.* Borneo. — **singapura** *Moore,* on the other hand, has according to the examples in my collection two strongly expressed double rows of white submarginal dots on the hindwing and in the ♀ distinct transcellular patches *sophia.* on the forewing. Singapore, probably also on the Malay Peninsula. — **sophia** *Moore* is rare in the alluvial plains of North-East Sumatra, but apparently rather common in the west of the island, and shows on both *limyrus.* surfaces somewhat brighter discal spots on the forewing. — **limyrus** *subsp. nov.* is a very dark island race with deep black instead of brown ground-colour, without transcellular spots and with small comma-shaped *staudingeri.* subapical patches on the forewing. Pulo Tello in the Batoe Islands. — **staudingeri** *Kheil.* one of the best known butterflies of Nias, is almost entitled to specific rank. Wings shorter, more rounded than in the preceding races of *aegyptus*. Forewing ornamented with large admarginal dots and a complete row of rounded, strongly expressed submarginal spots. Hindwing with a row and a half of small white marginal spots. Under *sticheli.* surface with white instead of violet discal spot. The ♀ must be very rare. — **sticheli** *Hag.* differs from the preceding chiefly in having all the dots of both wings reduced, neither above nor beneath larger than an entomological pin's head. Only the whitish discal spot on the underside of the forewing is very large, pointed-*rafflesi.* oval. Mentawej Islands, only ♂♂ known. *aegyptus* is wanting on Engano. — **rafflesi** *Moore* (84 a) is the more certain name for the Javan representative of *aegyptus*, which was perhaps first described as *ochsenheimeri Luc.* It occurs both in East and West Java, but is everywhere rare. It is met with in the coast-forests of Palabuan and in the mountain-ranges to the south of Malang, where, however, it is never found at over 500—600 m. above sea-level. Two principal forms may be distinguished, one with large, pure white subapical wedge-spots and grey-violet transcellular stripes on the forewing, corresponding to the description of *ochsenheimeri*, and the form here figured with the white spots of the forewing sometimes dusted with grey-

brown, which Moore has designated *rafflesi*. — **tricolora** *Fruhst.* (85c) is an astonishingly different race, of which three directions of variation may be noticed. **cuneifera** *form. nov.*, the principal form, which is figured, and to which are added in the name-type *tricolora* light violet transcellular, cellular and intramedian patches, so that such extremely richly coloured examples recall *margarita Btlr.* (84a). **rafflesina** *form nov.* is the name given here to examples with grey-blue instead of white subapical markings on the hindwing, which most nearly approach the Javan race. The three aberrations mentioned are reproduced in the ♀♀. Bawean, not rare from July to September. — **iduna** *Fruhst.* bears very little resemblance to *rafflesi* (of which I have large series before me), but, curiously, most nearly approaches *staudingeri Kheil* from Nias. *iduna* has in common with *staudingeri* the absolutely black ground-colour (brown in *rafflesi*), the equally prominent white spots on the forewing, which are divided in exactly the same way into two rows, whilst *rafflesi* shows only one row of washed-out whitish grey submarginal dots. On the hindwing *iduna* is even more copiously spotted with white than *staudingeri*, as the proximal white row of spots is also quite distinctly developed, whilst in *staudingeri* the second row is suppressed towards the anal angle, which is also the case in *rafflesi*. On the under surface of the wings *iduna* is intermediate between *rafflesi* and *staudingeri*. The spots on the forewing are stronger than in the former, weaker than in the latter. On the hindwing occur violet-white circumcellular dots, which are entirely absent in *staudingeri* and only indistinctly present in *rafflesi*. Kangean, in coll. Fruhstorfer. *tricolora.* *cuneifera.* *rafflesina.* *iduna.*

E. atossa *Pag.* much resembles *doubledayi* on the hindwing in the darkened, brown intramedian stripes, but naturally the scent-area is as in *rafflesi* and *tricolora*. Ground-colour of the forewing uniformly brown. The ♀ has sometimes two small violet costal spots on the forewing and on the hindwing in many examples the intraneural streaks show a tendency to obsolescence. ♂ beneath as above without subapical spots. Sumbawa. — **lombokiana** *Fruhst.* is a much smaller race, but with the white spots on the forewing more strongly expressed both above and beneath. Underside of the forewing with smaller violet submedian stripe and almost always with a curved row of well defined white subapical patches, which are absent in *atossa*. Lombok, at about 600 m., rare. *atossa.* *lombokiana.*

E. simillima replaces *aegyptus* and *atossa* on the Philippines and differs from the *aegyptus*-series chiefly in the light whitish or grey-brown intraneural areas of the hindwing beneath, which recall those of *leachi* (86c), *diana Btlr.*, and especially of the convergent Philippine *lucasi* and *swainsoni*. — **simillima** *Moore*, the North Philippine race, has no submarginal bands at all on the hindwing, but large white, almost quadrate subapical patches on the forewing. Very rare: Semper only knew 5 examples. Luzon. — **meldolae** *Moore* is characterized by smaller costal spots on the forewing, very long, prominent, pure white intraneural striae on the upper and under surface of the hindwing. South Philippines: Bohol, Mindanao. — **hypaspistes** *subsp. nov.* (the name signifies Esquire) is a race from Bazilan, where it occurs February—March. The white spots of both wings considerably reduced, the costal patches of the forewing in some examples powdered with brown. — **cornificia** *subsp. nov.* has the submarginal spots of both wings even more darkened and reduced. Mindoro. — **clorinde** *Stgr.*, from Palawan and Paragua, shows the admarginal dots of both wings dusted with brown, the submarginal spots of the hindwing are often absent. Palawan, not rare in January. — **aelia** *Fruhst.* belongs to those interesting relics of the land-connection between the Philippines and Borneo which still remain in the most notherly part of this extensive island and there inhabit Sandakan, whilst one degree further south the Macromalayan *aegyptus* already occurs in its place. *aelia* is smaller than *clorinde* and of lighter ground-colour. All the white markings are more washed-out and the number of the admarginal dots reduced. On the underside of the wings all the white dots and streaks narrower and smaller than in *clorinde*. *simillima.* *meldolae.* *hypaspistes.* *cornificia.* *clorinde.* *aelia.*

E. fabricii *Moore*, according to the description, is uniformly olive-brown above, the sexual spot of the forewing somewhat longer and placed nearer to the base than in *rafflesi Moore* from Java. The submarginal row of spots less strongly expressed, the marginal dots mostly absent. Hindwing with two rows of very minute spots, the proximal ones of which are obsolete from the upper median vein onwards. Cochinchina. Type in coll. Oberthür. *fabricii.*

E. dameli *Moore* is likewise unknown to me and is said to come from Shanghai, an extremely questionable locality, unless it is a northerly branch of the South Chinese *midamus L.* According to the description near to *aegyptus Btlr.* Upper surface washed-out brown, forewing with smaller, but prominent white subapical patches, a marginal row of five central and three lower very small spots on the hindwing. *dameli.*

E. midamus affords an interesting example of the variability of continental species and is next to *corus vitrina Fruhst.* the largest *Euploea* occurring in South Asia. Extraordinarily common in Hong-Kong and Siam, it becomes very rare at the limit of its range in Sikkim and Perak. Whether it also extends into the Macromalayan district is doubtful, but it is represented there by the forms of the *aegyptus*-series, whose relation to *midamus* is evidenced by *tricolora Frnhst.* from Bawean. — **midamus** *L.* (80a), a characteristic butterfly *midamus.*

of Hong-Kong and the adjacent mainland, passes in collections as *superba Herbst.*, *alopia Godt.* and *sinica Moore*. The last name refers to a form without pronounced double row of white submarginal dots on the hindwing, whilst *alopia Godt.* shows the maximum of white decoration, with still more extended light blue, white-centred transcellular and submarginal spots on the forewing than are shown in the figure. The ♀♀ are subject to the same variations, and that independently of the season, for at the end of October 1899 I took in the cemetery at Hong-Kong a ♀ with a white double row of spots on the hindwing above together with others without a trace of these spots. For the rest no two specimens are alike, in particular the spot before the apex of the cell on the forewing may be small, as on the figure, or 3 or 4 times as large. Also the discal spots of the forewing vary from light violet to dark blue, but a brilliant light metallic blue reflection is common to all. The ♂ butterfly smells slightly, the anal scent-pencils are dark yellow and very complicated, consisting of two rosettes, one very long-stalked with several long radiating hairs and the other a small, extremely delicate star at the tip of a somewhat lighter colour. According to Walker the larva lives on Strophanthus divergens, a climbing-plant of the family of the Apocyneae, on which the golden pupa also hangs. The larva is also occasionally found on imported oleander. The butterflies were repeatedly observed in groups of several hundreds, fluttering round the tops of flowering trees in the late afternoon. The true *midamus L.* extends to Tonkin and even to Central Siam, where I still took examples which could scarcely be distinguished from those from Hong-Kong. In Tonkin and Siam, however, *midamus* no longer predominates, but only occurs casually as an aberration. — That form of *midamus* which is common in the whole of Indo-China must be called **chloë** *Guér.*, though better known as **margarita** *Btlr.* (84a). It appears that *chloë (margarita)* is an intermediate form, which occurs in January-February, whilst I have taken *midamus* in November near Haiphong in Tonkin. The ♀ of *chloë* bears no white subcostal or discal patches on the fore-wing, moreover the discal blue spots are as a rule much less developed than on our figure. As **marseuli** *Moore* an individual aberration has been described from Saigon in Cochinchina, without white markings on the hindwing as in *chloë* and at the same time with conspicuous submarginal dots on the hindwing. — **brahma** *Moore* is an extreme dry-season form, in which in both sexes both the blue and the white irroration on the forewing are absent or reduced to a minimum and the dots on the hindwing are also somewhat reduced. Described from Moulmein, but occurring everywhere in Tenasserim and Siam. — **dejeani** *Moore* is an interesting melanotic local form, which approximates to *brahma*, as the almost unspotted forewing shows, but the hindwing is adorned with strikingly large double row of white dots. *dejeani* is, however, especially characterized by having the metallic sheen confined to the basal half of the forewing and dark steel-blue (instead of light blue). Malay Peninsula, from Pelak in my collection, according to Moore also occurring on Sumatra. But the latter locality, which rests on examples in the Boisduval collection, is very questionable. — **splendens** *Btlr.* from Nepal, is a well differentiated subspecies, characterized by the narrower forewing, and the constant absence of the white dots on the upperside of the hindwing, which though present beneath are much reduced. The light blue reflection similar, extremely intensive, recalling that of *Stictoploea harrisi*. *splendens* varies slightly according to the locality, the forewing in the Sikkim-♂♂ showing broadly diffuse, whitish-dusted transcellular strigae, in Assam-♂♂ (**irawada** *Moore*), on the other hand darker blue, more rounded patches. According to Nicéville *splendens* is extraordinarily rare in Sikkim, only occurring in the Terai and the lowest outer valleys of the Himalayas from April to November, but it is said to be somewhat commoner in Bhotan.

chloë. margarita. *marseuli.* *brahma.* *dejeani.* *splendens.* *irawada.*

E. klugi, in contrast to the Chinese-Further-Indian *midamus L.*, is more of an Anterior-Indian collective species, which is broken up into more sharply separated local forms, but in the centre of its range, in Assam, shows an even greater capacity for individual variation than *midamus-chloë*. Some extreme *klugi*-forms approach those of *chloë*,*) but they may be distinguished by the constant absence of the white and violet discal spots on the underside of the hindwing and by the more rounded wings. The ♂♂ are still further recognizable by the shorter, more rounded sexual stripes of the forewing and by a deep androconial cavity on the underside of the forewing, which is not found in the varieties of *midamus*. According to Moore *klugi* ascends northwards to Bhamo in Upper Burma, whilst in the south at Moulmein it is replaced by the Further Indian *crassa*. According to Bingham it also occurs on the Nicobars, but if the locality is correct, we may expect from there a still unnamed geographical form. Concerning the habits it is only known that in January and February it settles on sunny sandy river-beds near the edge of the water, in order to imbibe the moisture; but during the rainy season it prefers open places in the forests and foot-paths through the jungle. The new generation begins to appear in March, but in April and May it is commonest and freshest in appearance. I myself observed them in Siam always in groups on flowering shrubs which hung down over sandy river-banks. Moore figures as **klugi** a form with a large white spot before four blue-white ones beyond the cell and a row of very large wedge-spots inside a row of distinct white marginal dots on the forewing. — In **illustris** *Btlr.* all the cellular and circumcellular strigae are absent, on the other hand the anterior spots are extremely well developed, in **imperialis** *Moore* on the contrary the submarginal patches are most prominent. In **regalis** *Moore* the latter are very distinct on the

klugi. illustris. imperialis. regalis.

*) and especially also *Salpinx leniostictos leniogonys Btlr.*

hindwing also. **indigofera** *Moore,* founded on a small example, probably of the rainy season. bears also a white costal spot on the forewing. **hamiltoni** *Swinh.* is an aberration with incomplete series of white submarginal patches on the forewing, but distinct double rows of white dots on the hindwing. **augusta** *Moore* is darker blue with less blue reflection. **sherwilli** *Moore,* a rare form with confluant subapical and transcellular patches on the forewing, and **macclellandi** *Moore,* an interesting transition from *klugi* from Assam to *kollari Fldr.* from Sikkim with light violet discal patches on the forewing and a dark brown ground with dull blue reflection, very rare, first described from Assam, also before me from the neighbourhood of Calcutta. Finally, **uniformis** *Moore* even more approximates in the conspicuous median spots and the slight dark violet tinge on the upperside of the wings to **kollari** *Fldr.* The latter shows as a rule no violet reflection on the dark brown ground and bears very large white intraneural strigae on the upperside of the hindwing with round, pretty uniformly yellowish white submarginal patches on the forewing. Larva apparently not yet described, but is said to live on various species of Ficus and on Streblis asper Lom., an Urticaceae. Distributed from the southern point of the Indian peninsula to Bombay, but nowhere ascending above the coast. Near Calcutta it flies all the year round in company with the common *E. core Cr.* According to Hampson it occurs in the Nilgiri Hills even up to elevations of 5000 ft. — **sinhala** *Moore* is a darkened island form of the preceding, somewhat smaller, submarginal spots of the forewing strongly reduced and hence more isolated, admarginal dots mostly absent. The strigae of the hindwing likewise shortened. According to Moore *sinhala* has been found near Galla, but occurs especially at Kandy where it ascends to 1000 m., but is always very rare. — **crassa** *Btlr.* (= erichsoni *Fldr.*) (79 c) is the Further Indian representative of the species, which remains somewhat more constant in colouring and scheme of markings than *klugi* from Assam, yet in large series individual differences are shown, which gave rise to the erection of specific names, but which were recognized by its author in later years as mere forms, and placed as such. Butler's name-type has the submarginal patches on the forewing fairly equal in size and running in a complete row to the anal angle: the example here figured belongs to the form **apicalis** *Moore,* with large subapical spots, which are joined to the admarginal dots. — **masoni** *Moore* was found in Tenasserim at elevations of 3—5000 ft. and is a rainy-season form with the upper surface of the forewing suffused with dark violet. Hindwing with the submarginal patches reduced, otherwise as in *apicalis.* — **pembertoni** *Moore* has the submarginal spots traversing the entire forewing as in *crassa,* but very much less developed. Described from Lower Burma. — **burmeisteri** *Moore* is probably the product of an extreme dry season, the type is somewhat smaller than *apicalis,* with a double row of small yellowish white dots on both wings. Described from Saigon, taken by me in Siam in January and February. *crassa* is in Siam one of the commonest Euploeas up to 300 m. in hilly country. At the end of the dry season, January to about 25. February, only uniformly pale brown examples are met with, which but rarely have a slight violet reflection on the upper surface. But at the beginning of March, immediately after the first showers, the first generation begins to appear, dark brown and particularly at the base with violet-blue reflection. The apical spots are surrounded by rose-red to light blue margins, which become paler in the dry season, the approach of which was already foreshadowed by the rarity of the butterfly in August in Tonkin. According to a statement of Matsumura (Ent. Zeitsch., Stuttgart, 7. August 1909) a *Euploea* allied to *klugi* has been discovered on Formosa. — On Hainan *crassa* certainly occurs.

indigofera. *hamiltoni.* *augusta.* *sherwilli.* *macclellandi* *uniformis.* *kollari.* *sinhala.* *crassa.* *apicalis.* *masoni.* *pemberloni.* *burmeisteri.*

E. diocletianus is the only known species with grey instead of yellow hair-stars to the male anal pencils, which emit an agreable vanilla-scent. The butterflies are distinguished by sexual heterochromatism, which is shown in the island races in even more vivid contrast than in the continental forms. They are lively insects, like *Trepsichrois* love to be constantly on the move, never frequent wet places so far as I was able to observe, and are exclusively visitors to flowers. In Siam their appearance afforded especial pleasure on account of the pure white areas of the hindwing, as a wonderful contrast in the midst of the other exclusively dark species. Two local races occur in continental South Asia, otherwise the species is exclusively Macromalayan, not passing over to Bali and apparently not even occurring on Bawean. In vertical distribution it ascends to about 1000 m. — **ramsayi** *Moore* (81 a), described from Nepal and very local in Sikkim, only occurring in the deep outlying valleys from April to December. ♂ round-winged, upper surface with dark blue tinge in the distal area of both wings. — **diocletianus** *F.* (♀) (= rhadamanthus *F.* [♂]) differs from the preceding, particularly in the ♂, in the reduced white markings especially on the hindwing. On the forewing the transcellular white spots are sometimes entirely absent (**despoliata** *form nov.*). ♂♂ of the rainy-season form are larger than those which I collected in Siam in the dry season. Common everywhere from the Malay Peninsula to Lower Burma, from Assam to Annam. Examples from Sumatra and Singapore do not differ materially from those from Perak. — **lowei** *Btlr.* is an essentially darkened race, which occurs in Borneo; ♂ with only three, ♀ with four white subbasal stripes on the hindwing. ♀ predominantly dark brown. — **aërithus** *subsp. nov.* only differs from the preceding in the brilliant dark steel-blue tinge on the upperside of both wings in the ♀♀, and in the still shorter and narrower intraneural stripes of the hindwing in the ♂♂, hindwing of the ♀♀ with a double row of small white submarginal patches. Natuna Islands. — **alcidice** *Godt.* is a charming race from Java; ♂ scarcely differing from *diocletianus,* ♀ above somewhat lighter brown than

ramsayi. *diocletianus.* *despoliata.* *lowei.* *aërithus.* *alcidice.*

that of *lowei*, but hindwing more broadly striped with white and always with two rows of white submarginal dots. Common everywhere from the coast up to about 600 m. at the edges of woods and coffee-gardens
schreiberi. and flying all the year round, but never occurring in large numbers. — **schreiberi** *Bthr.* (= maasseni *Weym.*, niasica *Snell.*, niasana *Swinh.*) (81 c) is one of the most extremely developed melanotic island forms, giving the impression of a distinct species. Both sexes without basal streaks on both sides of the hindwing. ♀ dark brown with very narrow white bands, composed of isolated spots, at the apex of the cell and four small subapical and one anal patch on the forewing. Hindwing only with three small subapical spots. Nias, very
schildi. rare, especially the ♀. — **schildi** *subsp. nov.*, very common on the Batoe Islands, again more approaches the Sumatran *diocletanius*. The ♂♂ show basal white streaks on the forewing like those of *lowei*.

eupator. **E. eupator** *Hew.* (80 a), a very distinct species, probably replaces *diocletianus* on Celebes. In the
orneus. south of the island occurs a local race. **orneus** *subsp. nov.*, distinguished by even more widened white bands on both wings, especially in the ♀, in which also the white patch before the discocellular of the hindwing is twice as large as in *eupator* from the Minahassa. On the underside of both wings the white submarginal dots are more prominent. Flies in November: neighbourhood of the waterfall of Maros in the hinterland of Macassar.

Subfamily **Palæotropinæ** *(= Tellervinæ Fruhst.)*

Haase gave to this well defined subfamily, which only embraces one genus, the very significant name "*Palæotropidæ*" in contrast to the *Ithomiidæ* of South America = *Neotropidæ Schatz.*

According to the neuration it indeed most nearly approaches the South American Neotropids, but also differs considerably from these in the free costal vein of the hindwing, curving strongly upwards near the base of the wing and running just as in the Acræids, which never occurs in the Neotropids. Yet *Tellervo* has the broad cell and recurrent veins in common with *Ceratinia*.

But on the other hand the two subcostal veins arising before the end of the cell (in the Neotropids there is only one) form the most distinct point of agreement with the Danaids and, what is of greater importance, at the same time with the Satyrids.

The genitalia, however, do not reveal the least relationship with the Danaids, but rather point to a very close connection with the Satyrids. Hence the Palæotropids form an intergrade leading over from the Danaids to the Satyrids. Only the knowledge of the still undiscovered earlier stages can decide as to the proper place in classification. Probably the larva will be found to be cylindrical as in the Ithomiids and ornamented with short tubercles, and the pupa short, ventricose, but as in the Danaids with metallic gloss. Perhaps the larva lives on Solanum like the Ithomiid larvæ.

The genitalia reveal most connection with the Satyrids in the tripartite uncus and the simple, broad valve. The secondary sexual characters are little developed, thus especially the hair-pencils of the hindwing, so characteristic of the Neotropids, are absent, but the ♂♂ bear an elongate and broad area on the upperside of the forewing, which is adorned with modified scales and by which they can easily be separated from the ♀♀, which otherwise differ but little. Moreover, the costal margin of the hindwing is dorsally incurved.

In contradistinction to the *Tellervinæ* all the other Old World (and some New World) Danaids are classified as "Danainæ", which name should be inserted on p. 192 over the genus "*Danaida*".

1. Genus: **Tellervo** *Kirby (= Hamadryas Bdv.)*

Tibia and tarsus always present in the ♂. Forelegs, however, filiform, not clubbed as in the Danaids, from which *Tellervo* also differs in the longer basal joint of the palpi and the absence of the anal hair-pencil. Butterflies small, Ithomiid-like, with semitransparent, black- and white-spotted wings and long, delicate antennae gradually thickened into a club. Palpi projecting beyond the frons, densely haired, with a tuft of hairs on the middle joint and short, pointed terminal joint. — Concerning the habits it is only known that they are fond of the woods and fly irregularly and sluggishly. The genus is predominantly Papuan, with offshoots to the Solomons and westwards to the Moluccas. The commonly known generic name is preoccupied and hence Kirby's new name must be recognized. The poetical name *Tellervo* is from the Finnish language and signifies daughter of the forest god. The genus probably contains only one species.

zoilus. **T. zoilus** *F.*, the name-type, nearly approaches the figured *hiempsal* (78 e), but in ♂♂ of the rainy season the basal white cell-streak of the forewing is absent and the more rounded discal area of the hindwing is anally broadly scaled with blackish. A dry-season form copiously decorated with white has been
moorei. described as **moorei** *Macl.*; it has the disc. of the hindwing almost circular and the hyaline patches always more extended and purer white. Occurs only in northern Queensland, from Cardwell to Cape York. —
antipatrus. **antipatrus** *subsp. nov.* inhabits the southern part of British New Guinea and approaches the figured *zephoris* (78 e), from which, however, it differs in having the apical patches of the forewing almost twice as large

and a more oblong white area on the hindwing. Moreover, the scaleless transverse spot at the apex of the cell of the forewing is narrower and longer. — **hiempsal** *subsp. nov.* (78 e) inhabits Kaiser-Wilhelmsland. The ♀ differs from the ♂ in the more pronounced white spots of the forewing, especially the patch from the middle of the costal margin, which in the ♂ is either absent or only dot-like, is always well expressed. Together with the normal type-form figured occurs a rarer aberration with more rounded, distally convex, white discal area on the hindwing: **zephoris** *form. nov.* (78 e). According to Hagen *hiempsal* is common in open woods, and is a poor and feeble flier. Commonest in the rainy months of November and December, then again from March to June. I have received *hiempsal* in large numbers from the coast-forests at Friedrich-Wilhelmshafen. — Further to the east, in Finschhafen, we already meet with a different local race, **vereja** *subsp. nov.*, with very large, quadrate, pure white patches on the forewing, of which the transcellular are nearly confluent. — **fallax** *Stgr.* (78 e), not rare on Waigeu; the ♀ bears even larger white markings on the forewing, the subapical patches are nearly always confluent, the costal dot of the forewing always present and the transverse spot at the apex of the cell almost triangular. — **meforicus** *subsp. nov.* (78 e) is characterized by having the white median area on the hindwing strongly undulate distally, and with a long black tooth projecting into it from the costal margin opposite the end of the cell, as in *hiero*; Mefor. — **mysoriensis** *Stgr.* has the white patches on the forewing smaller and the discal area of the hindwing even more deeply incised; island of Mysore in Geelvink Bay. — **roonensis** *subsp. nov.*, a further very similar geographical branch of smaller size, with much narrowed white disc on the hindwing and dull vitreous areas on the forewing. Island of Ron. — **nedusia** *Hbn.* may best be compared with *hiempsal*, but is as a rule larger, with dull vitreous areas on the forewing and strikingly narrow, rectilineal band on the hindwing. From Dorey and Hattam, on the north-western coast of Dutch New Guinea. — **limetanus** *subsp. nov.* shows on the forewing very large rounded hyaline patches, which are otherwise darkened as in *nedusia*, and an irregularly defined and very broad pure white area on the hindwing. Discovered by Doherty at Kapaur, Dutch New Guinea. — **nais** *Guér.*, from the Aru Islands, has almost circular, large milk-white spots on the forewing, a distinctly curved discal spot on the hindwing and an elongate costal streak on the forewing above. According to Ribbe local, but not rare. — **niveipicta** *Btlr.*, a race inferior in size to *nais* with the white spots of the forewing more quadrate than round, and occasionally contiguous. The transverse area of the hindwing distally somewhat less excurved than in *nais*. According to Ribbe common in the woods on all the islands of the Key Group. — **jobinus** *subsp. nov.* is a further form allied to *nais*, but with indistinct costal spot, vertically placed cell-spot on the forewing, and band-like median area on the hindwing. The basal cell-stripe of the forewing is absent in the ♂, but is again present also above in the ♀. — **sarcapus** *subsp. nov.* is best compared with *hiempsal*. The cell-streak in both sexes very weak, the other white patches as in *meforicus*, the tranverse area of the hindwing distally deeply incised opposite to the median veins. Fergusson and Kiriwina. — **hiero** *Godm.* (= salomonis *Ribbe*) (78 e), distinguished by having the transcellular spots of the forewing fused into a band and a thin black longitudinal band, which cuts off a small oblong piece from the white discal area of the hindwing. Locality the Solomons, especially the Shortland Islands. — **assarica** *Cr.* (78 e), by far the most beautiful but also the rarest form of the collective species. It has been hitherto regarded as a separate species, but there is nothing to prevent its being united with *zoilus*, for the confluent spots of the forewing are also found in *hiero* and the strongly widened white discal area of the forewing is likewise no specific character, while the markings of the underside of the hindwing and the colouring of the abdomen agree with the other *zoilus*-forms. Ceram and Amboina. — **aequicincta** *Godm. & Salv.* has the most claim, perhaps, to be separated as a species, for in it the deep black ground-colour changes into a dull, but very dark brown, the scent-spots of the forewing are less sealed and hence more transparent. The white disc of the hindwing is not quite so rounded as in *hiero*, the white submarginal spots of the hindwing show through distinctly on account of the lighter and more transparent ground-colour. New Pomerania, New Lauenburg. — **variegatus** *Ribbe*, a somewhat larger local form with the vitreous spots of the forewing still more clouded. New Mecklenburg.

hiempsal. *zephoris.* *vereja.* *fallax.* *meforicus.* *mysoriensis.* *roonensis.* *nedusia.* *limetanus.* *nais.* *niveipicta.* *jobinus.* *sarcapus.* *hiero.* *assarica.* *aequicincta.* *variegatus.*

Appendix.

P. 202, to *Dan. melissa:* **nephthys** *subsp. nov.* approaches *orientalis Semp.* from Luzon, but is smaller, much lighter and more broadly striped with white, but with smaller submarginal patches than Semper's type. Sulu Islands, to the north of Borneo. — **sassina** *subsp. nov.* forms a transition from *palawana Fruhst.* to *orientalis Semp.* and is hence about intermediate between examples from Palawan and Luzon: relatively large, broadly striped and spotted with yellowish white. Mindoro, Cebu, Camiguin de Mindanao. Types in coll. Semper in the Senckenberg Museum in Frankfort. — **pelagia** *subsp. nov.* is in the same collection from the island of Cuyo and has the white stripes and spots still somewhat lighter and broader than *sassina*. — **tibula** *subsp. nov.*, from the Camotes, a strikingly dark form with broad black-brown marginal area especially on

nephthys. *sassina.* *pelagia.* *tibula.*

the hindwing and very small circumcellular and submarginal patches on both wings, and the hyaline spots
emona. decidedly less developed than in any other *melissa*-race from the Philippines. — **emona** *subsp. nov.,* from the island of Paragua, is again like *palawana,* near the *septentrionis*-type, and closely approximates to *microsticta*
valentia. *Btlr.* from Borneo in the arrangement of the strigae on the hindwing, but is somewhat lighter. — **valentia** *subsp. nov.,* likewise in the Semper collection, must be regarded as the largest race from the Philippines and is at the same time the most melanotic extreme of those forms which are more allied to Anterior Indian *septentrionis* than to the Micromalayan *melissa.* Abdomen of the ♂ above black, that of the ♀ red-brown. The greenish cell-spots nearly obsolete, especially the basal stripe of the cell of the forewing in the ♀. ♂ essentially darker than that of *palawana,* all the strigae, even those of the subapical region greenish. *valentia suanetes* is almost entitled to specific rank. Davao, Mindanao. — **suanetes** *subsp. nov.,* from the island of Balabac, resembles *microsticta Btlr.* from Borneo, from which it differs in the absence of the whitish basal streak in the cell of the forewing and is smaller and with more melanotic colouring throughout than Borneo examples. Type in coll. Staudinger in the Berlin Museum.

P. 204, to *Dan. ishmoides:* As the Philippines have produced in *tumanana Semp.* a *choaspes*-form, it is not surprising that the Celeban *ishmoides* also occurs there in branch-races. The new geographical subspecies in question are separable as follows, according to the material in the Semper and Staudinger collections,
trasinanus. where they are scattered about among the *melissa*-series: **trasinanus** *subsp. nov.,* from Cebu, where it occurs together with the *melissa*-race described above, is larger and far lighter than Celebes examples. The median spots of the forewing very large, on the other hand the fork in the cell of the hindwing is vestigial and in
sontinus. one ♀ entirely absent. Type in coll. Semper. — **sontinus** *subsp. nov.* inhabits Mindoro and is smaller than the preceding, with more delicate patches and lighter under surface. Type in coll. Staudinger. — Finally
strymon. **strymon** *subsp. nov.* is the largest, and as usual in Mindanao specimens the darkest form of the Philippines. more approaching the Celeban sister-race. Type in coll. Staudinfer.

moaria. P. 204, to *Dan. limniace:* The name **moaria** *subsp. nov.* may be given to the strikingly large Formosa race, which is distinguished especially from South Indian examples by the reduced subapical patches of the
norinia. forewing and the much thickened fork in the cell of the hindwing. — As **norinia** *subsp. nov.* we introduce the race from Hainan, in which on account of its small size the reduction of the whitish patches on both wings is still more noticeable.

oxynthas. P. 205, to *Dan. choaspes:* **oxynthas** *subsp. nov.* approaches *choaspes,* has the abdomen pure white with very thin, white dorsal line and differs from *choaspes* chiefly in having a narrow spot (scarcely half as broad) at the apex of the cell of the forewing. Sula Mangoli. Type in coll. Staudinger.

choaspina. **D. choaspina** *Stgr. i. l.* appears to be a species, as it has the spot on the forewing more than twice as broad as in *oxynthas* and the abdomen pure white. Occurs together with *oxynthas* on Sula Mongoli. Type in coll. Staudinger (Berl. Mus.).

caulonia. P. 205, to *Dan. aspasia:* **caulonia** *subsp. nov.* Approaches *thargalia Fruhst.* from West Sumatra more nearly than *kheili Stgr.* from Nias, but has in common with the latter the subapical strigae and the smaller size. The hyaline patches of the forewing become somewhat duller than in the Sumatra race, the median spots are not separated, but joined together. The white antemarginal and submarginal dots on the under surface are more delicate, as in Sumatran *thargalia.* Pulo Tello, in the Batoe Islands, near South-West Sumatra.
cerilla. — As **cerilla** *subsp. nov.* we separate the Palawan form, which approaches *shelfordi Fruhst.* from North Borneo, but is easily distinguished by the larger size and the corresponding increase in all the white patches of the submarginal and antemarginal areas. The ♂♂ are very similar to the Siamese *aspasia* ♂♂, but differ in
flymbra. having the submedian part of the forewing less tinged with yellowish. Type in coll. Fruhstorfer. — **flymbra** *subsp. nov.* is the race from Domoran, which differs from *cerilla* in showing the darkened coloration characteristic of the satellite-island forms. The innermarginal area of the forewing is more broadly yellow and of a darker shade and the yellow transcellular spots of the hindwing are much reduced. Type in coll. Semper.

meeki. P. 207, after *Dan. melusine:* **Danaida meeki** *Sm.,* from Fergusson Island, is said scarcely to differ in the ♂ from *melusine Sm.* from New Guinea, but to show a longer subapical vitreous stripe and to be of larger size. Under surface darker brown, the light band of the hindwing not placed so near to the base as in *melusine* and the subcostal stripes likewise more slender. Only 4 instead of 10—12 submarginal dots.

phormis. P. 208, to *Dan. aglea:* **phormis** *Fruhst.,* previously known only from Tonkin, Annam and Siam, also extends to Hainan; this race is distinctly different from the larger *maghaba Fruhst.* from Formosa.

P. 209, to *Dan. luzonensis:* Judging from the material in the Semper collection, the races of the
simonides. southern Philippines differ appreciably from the name-type from Luzon. As **simonides** *subsp. nov.* the Palawan subspecies especially may be separated, being essentially lighter and showing broader transcellular strigae and larger submarginal patches on the forewing. ♀ strikingly larger than the ♂. Types in coll. Fruhstorfer.

P. 210, *Dan. banksi:* **mnasippus** *subsp. nov.*, a strongly darkened form, easy to distinguish from *funeralis Btlr.* from Nias by the entirely black cell of the forewing, in which only a quite thin, linear hyaline marking remains. In addition all the strigae and submarginal spots are also much narrowed and reduced, especially on the underside of both wings. Batoe Islands. *mnasippus.*

P. 211, to *Dan. similis:* Like *aspasia caulonia Fruhst.* from the Batoe Islands the representatives of *similis* also differ from the Nias form, approaching the Sumatran branch-race. **ditiones** *subsp. nov.* differs from *macrina Fruhst.* from West Sumatra in the smaller size and the more delicate stripes and spots. Only in the ♀ the island melanism appears, in the more extended dark brown areas and the consequent reduction of the white striae and dots. *ditiones.*

P. 213, to *Dan. juventa:* **hadrumeta** *subsp. nov.*, judging from the Semper collection, is essentially darker and bears a more extended black marginal area than Luzon examples. Occurs on the Philippine Islands Negros and Bohol. — **tipasa** *subsp. nov.* is the race from Polillo and Leyte, a larger form, but less distinctly ornamented with hyaline markings on the forewing than Luzon specimens. Hindwing only with one row of whitish submarginal dots. *hadrumeta.* *tipasa.*

P. 216, under *Ideopsis gaura Horsf.:* Larva according to Dr. M. E. Piepers *in litt.* dark red-brown with a white ring at the edge of each segment. Two pairs of tentacles similar to those of the larvae of the *Danaida plexippus* group.

P. 222, to *Hest. leuconoë:* According to the long series in coll. Semper a further division of the Philippine *Nectaria leuconoë* becomes advisable. We mention first **athesis** *subsp. nov.*, from the island of Polillo, to the east of the Bay of Manila in Luzon, as a lighter form, with the forewing entirely yellow, but its apex much darkened in comparison with Luzon examples. Moreover the hindwing, in contrast to *leuconoë,* is only lighter in the distal parts. — **gordita** *susp. nov.* is a distinct race from Mindoro, which forms a transition to *obscura Stgr.* from Mindanao. But the examples are smaller, the yellow deeper than in *athesis* and more extended than in *obscura.* The black transverse band of the cell of the forewing twice as broad as in *athesis* from Polillo. — The island of Bohol, between Cebu and Mindanao, produces an allied form, **caesena** *subsp. nov.*, of pure white ground-colour, the base of both wings only slightly tinged with yellow. The cell of the forewing almost entirely black, differing from *athesis* in the still larger median spot, on the other hand the submarginal helmets of the hindwing more delicate. The ♀ reveals its connection with that of *obscura Stgr.* from Mindanao in the dense black scaling of the upper surface of the wings. — **fregela** *subsp. nov.* *athesis.* *gordita.* *caesena.* *fregela.*

is the conspicuously lighter form from the island of Siargao to the north-east of Mindanao, ♀♀ lighter than *obscura* ♀♀. On the forewing the basal yellow is absent and the hindwing has no black dusting — **vicetia** *subsp. nov.* is a still lighter race, forming a transition to *godmani. Oberth.* In particular the black cell-patches of the forewing are pure white, only narrower and longer than in the other Philippine races. The submarginal helmets of the hindwing more connected than in the Polillo form. Flies on the island of Domoran to the east of Palawan. Types of the above 5 raees in coll. Semper. In coll. Staudinger there is a race from the Sulu Island of Banguey allied to *nigriana Sm.* It is essentially darker than examples from Labuan in North Borneo. *vicetia.*

P. 223, to *Hest. blanchardi:* **munaënsis** *Fruhst.* was taken by Dr. Elbert in October 1909 also in the larger island of Buton, opposite to Muna. A ♀ in my collection differs from *phlegeton Fruhst.* (75 c) in having the forewing almost entirely blackened, with much larger cell-spots, and a somewhat more uniformly broad distal margin to the hindwing, which does not, as is *phlegeton*-♀, enclose any white wedge-spots. Also the under surface is darker than that of *phlegeton,* broadly black with silky gloss. *munaënsis.*

P. 231, to *Eupl. modesta:* **deriopes** *subsp. nov.* An extraordinarily dark race and so much larger than Siam and Tonkin examples of the collective species that I am still in doubt whether the single ♀ before me should not be united with *camaralzaman Btlr.* Forewing with 5 violet subapical patches, a costal and a violet transcellular spot, hindwing with indistinct, brown-shaded submarginal strigae, wich are essentially smaller and more obsolescent than in *modesta*-♀♀ from other localities. The distinct blue reflection on the upperside of the hindwing, present in all *modesta*-♀♀, is here absent. Under surface similar to the ♀♀ from Siam, only with darker and richer blue diseal patches on the forewing and the white submarginal spots of the hindwing reduced. Hainan, apparently rare, as it is not recorded by Moore, Holland and Crowley, who all wrote on Hainan butterflies. *deriopes.*

P. 227, to *Eupl. climena:* **moasana** *subsp. nov.* differs from *valeriana Fruhst.* in the narrower yellowish apical spot of the forewing and reduced whitish band of the hindwing. Island of Moa or Moas (east of Timor and Wetter). *moasana.*

P. 229, *Eupl. crameri:* **jedja** *subsp. nov.* Allied to *pryeri Moore,* also recalling *singaradha Fruhst.* from Bali, with strikingly large double row of white submarginal patches on the forewing; next to *pryeri* one of the most copiously white-dotted forms of the collective species. Banguey, type in coll. Staudinger, in the Berlin Museum, as also the preceding. *jedja.*

roduna. P. 231, to *malayica:* **roduna** *subsp. nov.* inhabits the small island of Banguey in the Sulu Group, to the north of Borneo, and is smaller, darker brown and more finely dotted than *scudderi Btlr.* from Borneo.

barea. P. 233, to *Eupl. alecto:* **barea** *subsp. nov.* represents the species in Duteh New Guinea, at Ati-Ati-Onin, in coll. STAUDINGER; smaller than *nox Btlr.* from Aru, with the rows of white spots on the upper surface strongly reduced and especially smaller discal and submarginal dots on the underside of both wings.

murena. P. 235, to *Eupl. funerea Btlr.:* **murena** *subsp. nov.* Considerably smaller than *funerea Btlr.*, of whieh it is a darkened satellite-island-race, with the yellowish submarginal band of the forewing strongly infuscated and the submarginal patches of the hindwing almost absent. Yule Island.

P. 235, to *Eupl. helcita:* Through the kindness of the director of the SENCKENBURG Museum in Frankfort on the Maine I have been able to examine two further sharply differentiated island races, both of which are *matilica.* represented by several examples in the Museum. **matilica** *subsp. nov.* surpasses even *eschholtzi Fldr.* from the Fiji Islands in the considerably widened white spots of the forewing and the larger and more complete series of subapical and antemarginal patches and dots. The hindwing bears a row of very long, proximally pointed strigae, plaeed in pairs, at the median veins and a complete row of larger admarginal dots. The prominent whitish violet diseal dots of *eschholtzi* and *aglaina* on the under surface are partially absent in this and the *lilybaea.* following race. Tahiti Paputi, in September. — **lilybaea** *subsp. nov.* forms a transition from *eschholtzi* to *aglaina Fruhst.,* the transcellular white areas of the forewing are more uniform, almost quadrate, the anterior are shorter than in *matilica*, the subapical spots as in *eschholtzi* and the hindwing as in *perryi Btlr.,* with complete double rows of small submarginal dots above. Colour of all the spots yellowish, not dazzling white as in *matilica.* From Tanna, in the New Hebrides.

hadrumaia. P. 236, to *Eupl. amymone Godt.:* **hadrumaia** *subsp. nov.* A race with the hindwing darkened, but the forewing more copiously dotted with white, from Hainan, where it is not rare. The form is especially characterized by the very large, pure white submarginal dots of the forewing above in the ♀♀ and the reduced submarginal strigae on both surfaees of the hindwing.

prunosa. P. 236: **prunosa** *Moore,* whieh from MOORE's description I took for a local form of *godarti Luc.*, is, judging from examples in coll. STAUDINGER, a representative speeies or highly developed rainy-season form of *amymone.* It appears that STAUDINDER obtained the name *prunosa* from OBERTHÜR, who is in possession of MOORE's type. *prunosa Styr.*, indeed, by no means agrees with the description of *prunosa Moore*, but as apart from this it is probable that *prunosa* will sink as a synonym of *amymone Godt., kinbergi Wallgr., lorquini Fldr., felderi Btlr.*, while on the other hand these four names may probably have to be divided between two species, the name *prunosa* is here retained in STAUDINGER's sense until I have the opportunity of verifying the types of the several forms in England. In the meantime the STAUDINGER collection is accessible to everyone, so that comparisons can easly be made. *prunosa* differs from *amymone Godt.* and from the examples thus labelled in coll. STAUDINGER in its larger size, the longer sexual stripes of the forewing and the absence of the white antemarginal dots on the underside of the hindwing. Hong-Kong and South *tersatica.* China. — As **tersatica** *subsp. nov.* I would designate the representative from Hainan, to whichever name-type it may ultimately prove to belong. It differs from *hadrumaia,* whieh flies together with it, and of which also the more northerly name-type has not yet been settled, like the Hong-Kong form in the larger size of both wings and compared with *prunosa* from Hong-Kong and *hadrumaia* from Hainan in the reduction of the white dots on the upper surface. The hindwing bears above no white dots at all and the submarginal patehes of the forewing in the ♀♀ are not pure white, but tinged with blue or violet. Hainan, not rare.

lucania. P. 237, to *Eupl. alcathoë:* **lucania** *subsp. nov.,* nearly allied to *simplex Fruhst.* from Nias and forming the transition from this to the West Sumatran *vonara Fruhst.* The ♂ similar to *simplex,* but with somewhat more pronounced grey-white striae on the upperside of the hindwing. The ♀ smaller than that of *vonara,* with narrower intraneural stripes, slightly scaled with grey-brown, on the hindwing. Pulo Tello in the Batoe Islands, off the west coast of Sumatra.

jadiva. P. 239, to *Eupl. swainsoni:* **jadiva** *subsp. nov.* is a melanotie island raee, approaehing *butra Styr.,* but with the white patches reduced. Balabac. — The Berlin Museum (coll. STAUDINGER) possesses a ♂ of *dono-* *bevagna.* *vani Fldr.* from the Minahassa, colleeted by Dr. PLATEN; henee the locality Celebes is eonfirmed. — **bevagna** *subsp. nov.* is nearly allied to *donovani,* but has a broader sexual stripe on the forewing, the white patches of the forewing are larger and have the blue bordering more extended and with a brighter gloss. Island of Sangir.

nicaias. P. 240, to *Eupl. diana:* **nicaias** *subsp. nov.,* judging from the ♀♀ in coll. STAUDINGER, nearly appoaches *tombugensis Fruhst.* from East Celebes, but has a paler brown ground-colour and the white spots on both wings less developed. Bangkai.

P. 247, to *Eupl. dufresne:* On the Philippines oecur two very interesting forms of this species, as is sufficiently evideneed by material in eoll. STAUDINGER. On almost all the Philippines there is only one

Stictoploea, resembling the figured *laetifica* (82 a). On Mindoro and Mindanao occurs in addition a second *Stictoploea,* which was recognized as a distinct form by Staudinger and Semper, and which they called *tyrianthina.* In this so-called *tyrianthina* the white subapical patch of the forewing is absent and it is also smaller than *dufresne.* These examples, however, differ considerably from true *tyrianthina* in the brighter blue sheen on the upperside of the wings. It is almost certain that this hitherto erroneously designated form is entitled to specific rank, and I would propose for it the name **praeclymnias** *spec. nov.*, as Mindanao produces an *Elymnias* species showing a tendency to vary in the same direction, namely *Elymnias beza Hew.* The well known typical form of this may be regarded as analogous to *Euploea praeclymnias,* whilst a rarer form approximates to *dufresne* in the large white subapical spots of the forewing. Both fly together on Davao, East Mindanao, where Dr. Platen discovered them. *praeclymnias.*

P. 248, to *Eupl. gloriosa:* As **agapa** *subsp. nov.* we introduce the race from Bankai, which is inferior in size to the North Celeban name-type and may be easily recognized by the smaller patches on the upper surface of the wings. *agapa.*

P. 252, *Euploea mazares Moore:* Larva discovered by Dr. Piepers on Java, with 3 pairs of tentacles and of dark violet ground-colour with yellow abdominal stripes.

P. 253, to *Euploea mazares:* **cabeira** *subsp. nov.,* a local form from south-eastern Borneo and easy to distinguish from *aristotelis Moore* from the north of the island by the darker and more glossy blue. In the larger white subapical patches of the forewing above and the pronounced double row of white submarginal dots, moreover, *cabeira* approximates more to *mazares Moore* from Java than to *aristotelis* (type in coll, Staudinger). — **gamala** *subsp. nov.* approaches *palawana Fruhst.,* but is smaller, darker blue and with the subapical dots even more reduced, in the ♀ almost entirely suppressed. From Paragua near Palawan. Type in coll. Semper. *cabeira.* *gamala.*

P. 255, to *Eupl. hopfferi:* **cluilia** *subsp. nov.* forms a transitition from *hopfferi Fldr.* to *helia Fruhst.* from Banda, is of dark brown ground-colour and has a much narrower whitish distal margin to both wings. The apical patch is more extended brown and cuts more deeply into the submarginal band than in *hopfferi,* so that this band is distally more deeply excised. Island of Tjandoe in the Key Group. *cluilia.*

P. 262, to *Eupl. negleyana:* This race from Hainan has now reached me in numbers and by its variability has led me to relinquish my belief in the specific independence of *klugi Moore* (p. 270) and to attach this well-known Assam *Euploea* to *leucostictos Gmel.* as simply a geographical race. *coelestis Fruhst.* (83 b), discussed on p. 262, distinctly forms the transition from *leucogonys* to the insular *negleyana* and to the continental *klugi.* Among *klugi* in my collection there are several examples which can scarcely be separated from *leucogonys.* ♂♂ also occur on Hainan in which the wedge-shaped, white-sprinkled discal spots and delicately blue transcellular ones specially mentioned by Holland are wanting (**leucostictina** *form. nov.*), and in Assam there occur similar examples, which are further characterized by the absence of the blue or violet sexual spot between the lower median and the submedian on the forewing. But neither Moore nor Butler has mentioned or described specimens of this description and strange to say they have never been figured. Of the aberrations classified under *klugi, crassa Btlr.*, p. 271, should be separated and raised to specific rank. To it belong, besides *sherwilli, macclalandi* and *uniformis Moore,* all the forms specified after *kollari.* *leucostictina*

P. 263, to *Eupl. leucostictos:* **marea** *subsp. nov.* forms the transition from *juno Stich.* from Nias to *phane Doh.* from Engano. The ♂ only differs materially from *phane* in the greatly restricted blue reflection on the hindwing, which scarcely extends beyond the cell. The ♀ approaches that of *juno,* bearing the aspect of a slightly darkened variety, with the white centres of the subapical spots of the forewing reduced. Batoe Islands *marea.*

P. 264, to *Eupl. viola:* The description of *leochares* may be completed from a pair collected by Kühn on Saleyer: smaller and darker than Celeban *viola,* the transcellular and subapical spots relatively small, predominantly white with blue bordering. Under surface approaching the South Celeban *westwoodi,* but with smaller spot.

P. 268, to *Eupl. aegyptus:* **bazares** *subsp. nov.*, an interesting race, remarkably similar to *atossa Pagenst.*; hindwing above with the diffuse spots only indicated, as if showing through from the under surface, but very large and powdered with grey-brown. Under surface of the hindwing with only one row of submarginal patches and two subapical whitish punctiform spots. Mindanao, discovered by Dr. Platen. *bazares.*

P. 269, to *Eupl. atossa:* **giva** *form. nov.*, from a ♂ in coll. Staudinger, recalling *tricolora Fruhst.* from Bawean, with three large blue-white transcellular patches and unusually large, wedge-shaped subapical patches on the forewing. Sumbawa. *giva.*

P. 269, to *Eupl. midamus:* **aegumurus** *subsp. nov.* approaches *sinica Moore.* from which it differs in its smaller size. From *midamus L.* from Hong-Kong the new race is likewise distinguished by the lesser expanse of both wings and still further by the uniform rows of pure white, submarginal intramedian spots on the *aegumurus.*

hindwing, which are scarcely half as broad. The white and blue spots on the upperside of the forewing are also reduced. Hainan.

P. 271, to *Eupl. crassa Btlr.:* The abandonment of *klugi* as a species and its union with *leucostictos Gmel.* and the separation of *crassa* as a distinct species affects the status of several forms. Thus *kollari Fldr.* is a very distinct geographical race from South India, and disfributed as far as the outer and lower valleys of Sikkim. *sinhala Moore* is the well differentiated branch from Ceylon, and I suspect that Bingham refers to a *crassa*-from when he speaks of a *klugi* from the Nicobars in the "Fauna of India." *macclelandi Moore* would then be the oldest name for the Assam subspecies, which already occurs singly as an aberration in Sikkim, and *sherwilli Moore* also no longer belongs as a form to *klugi*, but is to be treated as an aberration of *crassa* with confluent apical and subapical patches on the forewing. *uniformis Moore* must be considered as a form of *crassa*, with essentially smaller submarginal and antemarginal patches than *kollari* and differing from *macclelandi* in the absence of the median spots on the forewing; it should therefore be removed from the *klugi* series of forms. The other forms enumerated on p. 171 after *kollari* remain unaltered.

thrasetes. P. 272, to *Eupl. eupator:* **thrasetes** *subsp. nov.* inhabits Saleyer and is smaller than South Celebes examples, with more delicate white strigae on the hindwing. Type in coll. Staudinger, discovered by H. Kühn. —
sardes. **sardes** *subsp. nov.* Larger, darker blue than Celebes-♂♂, with a second row of white subapical strigae on the forewing. Cellular and transcellular patches isolated, because smaller than in *eupator Hew.* from North Celebes.

faesula. P. 279: *Eupl. barsine Fruhst.* is preoccupied twice, hence on p. 233 the name **faesula** should be substituted.

distinctissima. P. 279: *Eupl. distincta Stgr.*, preoccupied by Butler, should be changed to **distinctissima** *nom. nov.*

Alphabetical List

with reference to the original desciptions of the forms of the Indo-Australian *Danaidae.*

* signifies that the form is also figured at the place cited.

4. Family: Satyridae.

The morphology and biology of this cosmopolitan family have already been sufficiently dealt with in the Palearctic part (vol. 1, p. 79) and in the discussion of the South American forms (vol. V, p. 173), so that only a few points peculiar to the tropical Asiatic Satyrids remain to be treated of here.

A sharp differentiation of the Satyrids from the following family (the Amathusiids) is almost impossible, especially as regards the larval form and that of the sexual clasping-organs, and Haase's erection of the group of Satyromorphids, to which reference has been already made in the Palearctic part, is constantly receiving fresh support as our knowledge increases.

There is also some resemblance to the Danaids, but more in the coloration than anatomically, for the clasping-organs approximate much more to the Nymphalids than to the Danaids. In general the occurrence of convergences is a characteristic of the Satyrids and the perfect imitations of the genus *Elymnias*, that paradigm of the adherent of the mimicry theory, never ceases to call forth our astonishment.

In accordance with the retiring habits of the shade-loving Satyrids all, probably without exception, have a weak flight and they prefer the underwood, though some species follow the cultivation of the rice in South and East Asia and others prefer open pasture-land. The species are for the most part of uniform colouring and their habit of dropping after a short flight and even settling obliquely, heightens their resemblance to dry or rotten leaves. But together with monotonously coloured groups of species we also find, in the great forest regions, species clothed in the glossy blue of the Euploeids (*Coelites*, *Ptychandra*), while others wear the hyaline white of *Hestia* and *Ideopsis* (*Zethera*, *Elymnias*), and the Australian species have in common a peculiar ochre-yellow colouring, probably adapted to their sterile environment. Pure reds and greens have not yet been recorded, but several New Zealand and insular species have metallic decorations on the under surface. A commonly recurring scheme is white, yellow or brown oblique bands on the forewing.

The clasping-organs are as a rule of the simplest structure, and in most cases even without essential differences between the Palearctic and the tropical genera. The long, distally pointed uncus bears two lateral clasps, slightly curved upwards, the valve is always provided with bristles and more or less broad, mostly with simple top, only rarely armed with teeth. The only exception is the genus *Zethera*, the valve of which bears dorsally an appendage shaped like a snake's head, into which the point of the uncus can be pushed. Jullien's rods, i. e. bundles of bristles welded together as in the European *Eumenis fagi* (= *Satyrus hermione*) and *alcyone* have not yet been observed in the Asiatic species. Only in certain *Maniola* (*Epinephele*) there are similar rods, but of smaller extent, and in *Eumenis* (*Satyrus*) *semele* from North India dorsal or subdorsal tufts of fine hairs are found, remotely recalling the scent-hairs of the Danaids. The organs are the most simplified in *Melanitis*, in which the lateral points of the uncus are wanting and the valve shows the simplest structure.

In the development of the secondary sexual characters the Indo-Australian Satyrids are behind the South American and even the African, on the other hand sexual dimorphism and heteromorphism is developed to an almost unparalleled extent. Some species of the genera *Elymnias* and *Zethera* even lay aside their family garb in order to assume more completely the style of colouring of the models from other families. That the members of so weak and pliant a family as the Satyrids should also be in the highest degree susceptible to climatic influences is only natural. Some species of the genera *Mycalesis* and *Ypthima* are actually so modified by the influence of the contrasting seasons as to be unrecognizable, and it is almost impossible in female examples of the dry-season form to settle their identity with their ♂♂ or to separate the different species. Many Satyrids are locally confined to isolated mountain peaks, single valleys and also islands. Ubiquitous species are relatively rare and become increasingly so as we proceed eastwards, breaking up into good species. In their vertical distribution they resemble many Pierids and Nymphalids, as they ascend to 4000 m., leaving far behind them the Danaids, which scarcely reach 2000 m.

The most striking and beautiful species prefer the woods in the hot lowlands of the coast-district, yet the number of species scarcely decreases at elevations of 1000—1500 m.

In general the Satyrids in the tropics do not present to the eye the same lively picture which is displayed in the height of summer on our meadows and woodlands. The relative poverty of tropical Asia is doubtless due to the absence of the more tender Gramineae, these being supplanted by the ill-famed lalang grass which is unpalatable to most larvae. In addition to this, the tropical wood does not produce grasses and their giant relative, the bamboo, apparently serves as food-plant only to the genus *Lethe*. But in those subtropical

districts where grassy plains are found, the situation is changed; thus in Sikkim occur 17 genera and 75 species, whilst in the equatorial forest-land of Sumatra only 10 genera with 36 species are known.

The figures are drawn from examples in coll. Fruhstorfer, Genf-Florissant, with three exceptions, which the Tring Museum kindly placed at our disposal. The types of the new forms are likewise in the Genf collection except where it is specially noted to the contrary.

Ypthima - Group.

Small delicate butterflies of the size of the European *Coenonympha*, with a large subapical ocellus on the forewing, which extends between the radials and the upper median. The under surface of the butterflies is never striped, but unicolorous or finely striated or irregularly spotted. The costal vein is always inflated.

1. Genus: **Ypthima** *Hbn.*

Next to *Mycalesis* the most extensive genus of the eastern tropics, at the same time bicontinental, as it encroaches into Africa and one Indian species has spread through Persia into Palestine. Also the Palearctic north of East Asia produces a few species.

Forewing with only one subcostal before the end of the cell, lower discocellular of the very broad hindwing runs into the bend of the upper median vein. Both the costal and the median vein inflated. Precostal of the hindwing short, knobbed. Some species bear a rather broad sexual spot, with a dull gloss, on the forewing, the presence or absence of which has been utilized for dividing the genus into groups; but the very constant arrangement of the ocelli on the hindwing beneath is much more essential for this purpose. — Larva according to Moore in „Lepidoptera Indica" somewhat less than an inch long, entirely green, the head round, the body of nearly uniform width, becoming somewhat thicker at the fifth segment, and then tapering to the anal segment, which bears two immovable divergent processes. Head and body covered with small, fine, colourless hairs, which arise from soft tubercles. — Pupa either green or brown, the head rounded, the wing-cases somewhat raised and anteriorly angled, the thorax humped.

Ypthima are but little dependant upon the sun and appear even on dull days in the early and late evening hours. In neglected coffee-gardens on the plateau of Pengalengan in West Java I met with them in hundreds on and between the weeds even in rainy weather. They all keep low in the grass, settling on blades and leaves but not on the ground. They are fond of visiting Ixora and Sambucus umbels and even sit on the flowers with the wings spread out. At elevations of 1500 m. they are still very common and it is known that in the Himalayas some species occur up to 8000 ft. The head-quarters of the genus are subtropical China and the whole of India. In the Macromalayan region they begin to decrease rapidly in numbers, and Sumatra and Java produce only 5 species; from Australia only one species is known, and in the Bismarck Archipelago and the Solomons they are entirely absent.

Y. asterope has already been discussed in the Palearctic part, but in place of it a strikingly small *baldus*-form is there figured (34 a), while a whole series of varieties of this species is found in vol. XIII on pl. 28. *asterope* always bears only one anal ocellus on the hindwing above, and beneath in the rainy-season form only one apical ocellus is present, never two. In the dry-season form, **alemola** *Swinh.*, even these disappear, so that the hindwing is plain grey-sand-colour without any markings except the unusually fine striation. — **asterope** *Klug* is the North African and Syrian branch of the collective species. — In the Himalayas, Kulu (Kashmir), thus in the Palearctic Region, occurs the smaller **mahratta** *Moore*, at elevations of from 2000 to 6000 ft. — In Further India, in the south of Annam, I found a dry-season form with smoke-brown under surface, likewise without eye-spots, **annamitica** *subsp. nov.*, which there ascends to about 1600 m. above sea-level and flies on the driest grassy places in large numbers even in the hottest part of the day. — As **norma** *Westw.* an aberration from China has been described, in which the apical eye-spot of the forewing is absent above.

alemola. *asterope.* *mahratta.* *annamitica.* *norma.*

Y. inica *Hew.* is an allied species, whose type is based on an example of the dry season, of which **complexiva** *Swinh.* is an aberration in the ocelli resp. an intermediate form. The rainy-season form **ariaspa** *Moore* (= rara *Btlr.*, daedalea *Swinh.*) only differs from that of *asterope* in having a larger anal eye-spot on the hindwing beneath. Examples of the dry-season form, however, can scarcely at present be distinguished from *alemola*. Punjaub, Central India, where it is not rare from May to November.

inica. *complexiva.* *ariaspa.*

Y. arctous *F.* (99 c), another primitive species, with the eye-spots of the simplest development, a larger apical ocellus on the forewing and a smaller one, which is sometimes nearly obsolete, in the anal angle of the hindwing. Under surface smoke-brown, with still more uniform vertical striation than *asterope* and no traces of longitudinal bands. Australia. — **papuana** *subsp. nov.* is smaller than *arctous* and is much darker brown both above and beneath. According to Hagen not rare on the grass at the road-sides, but local. Flies especially in December and March. New Guinea.

arctous. *papuana.*

Y. florensis *Snell.* (99 c) is light grey beneath and differs from *arctous* in the large, circular apical ocellus on the underside of the hindwing. But on the upper surface of the hindwing the eye-spot, which is so distinct in *arctous*, only shows through. Flores. *florensis.*

Y. pusilla *spec. nov.* (99 c as *minuta*) is probably the smallest Asiatic species, and was referred to *asterope* by Rothschild, Holland and Doherty. Above even somewhat lighter grey than *florensis* and beneath easy to recognize by the double eye-spot on the anal area of the hindwing. South Celebes, from the lowlands up to 1000 m. January, March. Amboina. The name *minuta* must sink, being preoccupied by *Y. minuta Matsumura* from Formosa 1910. *pusilla.*

Y. huebneri is widely distributed in continental South Asia and may be easily recognized by the three contiguous eye-spots on the underside of the hindwing. — **kasmira** *Moore*, very well figured in the Palearctic part (34 a), is the most northerly branch-race of the species. — **jocularia** *Swinh.* is a very distinct pale form from Western India with the anal area of the hindwing above slightly tinged with violet, and **honora** *Moore* (= apicalis *Moore*, catharina *Btlr.*) is the dry-season generation without ocelli on the underside of the hindwing. — **huebneri** *Kirby* (99 e) is the race from the eastern Himalayas, where the form occurs as far as Burma. The example figured came from Annam, where this form flies in the plains, whilst in Tonkin it ascends to about 3000 ft. The ♀ is paler grey, above like that of *baldus*, but with rounder wings. Egg a beautiful light green, the larva hatches in 4 days and soon produces a green or brown pupa, from which the imago emerges after about 4 weeks. According to Nicéville's observations, however, the development is more rapid in November-December, the pupa yielding the butterfly in only 12—18 days. The larva is described in the generic diagnosis. *kasmira. jocularia. honora. huebneri.*

Y. ceylonica *Hew.* (99 e) is the only species with the hindwing almost entirely white. The example figured belongs to the dry-season form **gellia** *form. nov.*, whilst Hewitson described the form of the rainy season, which has larger eye-spots, these being arranged beneath exactly as in *huebneri* and almost as large. *ceylonica* was formerly only known from the island whose name it bears, but it has now been discovered also in Southern India, in a slight variety. Its flight is short and it rests at the roadside on grass and weeds. Elwes and Edwards consider *ceylonica* to be specifically distinct from *huebneri* on account of the great differences in the finely denticulate apex of the valve. *ceylonica. gellia.*

Y. jarba is a species discovered simultaneously by Dr. Martin and myself, and of which Nicéville also received a doubtful form from Manipur. — **jarba** *Nicév.*, described from examples from Sumatra, is about intermediate in size between *gaugamela* (99 d) and *eupeithes* (99 f) and as may be seen from a glance at the unequal size of the anal ocelli and the dissimilar longitudinal striation, cannot be regarded as allied to *baldus* or *huebneri*. *jarba* is very rare and in 13 years Dr. Martin has not been able to obtain more than 12 examples. — In West Java and there only in the mountains from 1000 m. upwards *jarba* is replaced by **eupeithes** *subsp. nov.* (99 f), conspicuous by its size, the whitish median area of the hindwing and the large eye-spots with broad ochre-yellow margins. Examples also occur with an accessory eye-spot at the apex of the hindwing beneath. ♀ fully a third larger than the ♂. Flies April to June, on Mount Gedé and the plateau of Pengalengan, West Java. — **gaugamela** *subsp. nov.* (99 d). Above darker brown than *eupeithes*, the longitudinal bands on the under surface of the forewing straighter. The hindwing shows no accessory ocellus, the median area is more broadly striated with black than in *eupithes* and the habitus much smaller. East Java, from 500 m. upwards. Very rare. *jarba. eupeithes. gaugamela.*

Y. philomela *Joh.* (99 c). The synonymy of this species is in great confusion; all that is certain is that *tabella Marsh.*, *baldus Elw.* and *huebneri Snell.* are identical with it. *huebneri Kirby*, Seitz p. 91, is not the same. *philomela* occurs in South India, where it ascends to 3500 ft., in Java and Sumatra, in coll. Fruhstorfer there are also examples from Perak and Sumbawa. *philomela* differs from *huebneri Kirby* in that in the anal angle of the hindwing there are only 2 principal ocelli and but rarely one or two punctiform accessory eye-spots, whilst *huebneri* bears three anal ocelli of equal size. Moreover, the anterior ocellus in *huebneri* is always isolated, whilst in *philomela* it is almost without exception accompanied by a small supplementary eye-spot. On the upper surface *philomela* differs from *huebneri* in having a smaller apical eye-spot on the forewing. — Moore has described as **indecora** the somewhat larger race from North-Western India, which bears larger apical ocelli on the forewing and also above large anal eye-spots. Dry-season examples occur with the under surface dark sand-grey, often without the least trace of eye-spots. Kulu, Kangra (Kashmir), Mussouri. The form also approaches *philomela* in the structure of the valve; but according to Elwes it differs from it in having a distinct sexual spot on the forewing. In dividing the collective species I have here followed Bingham. But concerning *philomela* itself there is no doubt; it was originally described from Java and is extremely common both in the east and west of the island up to elevations of about 700 m. *philomela. indecora.*

Y. fasciata, one of the most easily recognized species, of which there are only two races to mention. — **fasciata** *Hew.* (99 g), described from Borneo, in my collection from Pontianak and the Natuna Islands, is conspicuous for the chain-like series of six eye-spots of almost equal size on the hindwing. The upper surface *fasciata.*

is dark brown, the apical ocellus of the ♂♂ relatively small, sometimes oblong, that of the ♀♀ large, with distinct
torone. white pupil and broad yellow bordering. — **torone** *subsp. nov.* differs in having the under surface of both wings light grey instead of striated with brown, as Distant already pointed out in 1883. Very rare, Perak, North-East Sumatra and the neighbourhood of Padang in West Sumatra.

lisandra. **Y. lisandra** *Cr.* (99 e), although first described as long ago as 1782, is one of the rarest and least known species. There are two forms of the ♂, the normal one, with a small apical eye-spot on the forewing, and the rarer one figured, without this. On the under surface the oblong apical ocellus has two distinct white pupils, the hindwing shows 2 apical and 2 subanal eye-spots, narrower and margined with darker yellow than in *baldus*, while in the anal angle, but placed less proximally, there is one other ocellus, never two as in *baldus*. Moreover, the whole under surface is darker brown, with more uniform and finer transverse striation than in *baldus*. Collected by me in Tonkin, Manson Mountains, April-May at about 1500 m., also from Hong-Kong in my col-
micromma-tus. lection. — **micrommatus** *Holl.*, described from Hainan, is an interesting local race; judging from the figure it is an intermediate form, lighter grey than *lisandra*, with smaller ocelli on the hindwing beneath. The fore-
minuta. wing bears the small apical eye-spot which is so characteristic of normal *lisandra*. — **minuta** *Mats.*, described from Formosa, probably also belongs here, unless it proves to be a form of *asterope* or *huebneri*.

avanta. **Y. avanta** *Moore* is an extremely variable species, but little distributed in continental collections, which inhabits almost the whole Indian Empire from Kashmir to Tenasserim and has advanced beyond the south-
ordinata. ern extremity of India to Ceylon. The name-type is the dry-season form, from which **ordinata** *Btlr.* of the rainy season differs in its larger size and the larger ocelli on the under surface, which are arranged much as
cerealis. in *baldus*. The dry-season form bears, as in *baldus*, two brown longitudinal bands on the under surface. — **cerealis** *Wats.*, described from the sterile region of Upper Burma, is a well defined local race, coming from a district entirely without trees; smaller than the Himalayan form, with the under surface clear white instead of slate-grey
striata. and almost without longitudinal bands. Androconia nearly absent on the forewing above. — **striata** *Hmps.* is still smaller, beneath likewise whitish, but with distinct submarginal brown longitudinal bands. The striation more delicate than in *avanta* and the yellow bordering of the ocelli more strongly expressed. The dry-season form as usual has the eye-spots much less developed. From 2—4000 ft., in the Nilgiris, the rainy-season form
singala. appearing in August, the other in December and January. — **singala** *Fldr.* (99 c) is somewhat darker than *avanta*
thora. with less of the purple gloss. Upper surface sometimes without eye-spots. **thora** *Moore* is the dry-season form with the ocelli on the underside of the hindwing reduced. Rare in Ceylon, flying about long grass at the edges of coffee-gardens and occurring at about 1000 m. The West Chinese *avanta*, already mentioned in vol. 1, p. 92, will certainly prove to be different from the North Indian race.

ypthimoi-des **Y. ypthimoides** *Moore* (= robinsoni *Dist.*) (99 d) is a species peculiar to South India, that home of so many endemic forms. Colouring of the upper surface dark brown throughout, with a bi-pupilled apical ocellus, constricted in the middle, and two eye-spots on the hindwing, somewhat larger than mere dots. The ♀ is lighter than the ♂ and shows clearer yellow bordering to the eye-spots of the forewing. The under surface of the hindwing is traversed by a weak, narrow, grey-white longitudinal band. *ypthimoides* shows a preference for grass-covered peaks at altitudes of 1000 to about 1500 m.

chenui. **Y. chenui** *Guér.* (99 d), of which we figure the dry-season form, shows a very large, as it were flattened-out, apical eye-spot on the forewing, bi-pupilled with blue and broadly margined with a beautiful light yellow. Hindwing with one or two punctiform spots. The wet-season brood is adorned with distinct ocelli on the underside of the hindwing. Common on rocky hills. Four generations are known in the year and the butterfly is never met with below 5000 ft., but ascends to 6700 ft. Locality hitherto only the Nilgiris in South India.

zodia. **Y. zodia** *Btlr.* (vol. 1, p. 91, 34 a) belongs to the same series of forms as *chenui*. — **albescens** *Pouj.* is very
albescens. likely the rainy-season form of *zodia*, of which I have before me only examples without eye-spots. West China.

bolanica. **Y. bolanica** *Marsh.*, above umber-brown, with an oval, oblique, bi-pupilled ocellus. Hindwing above with a small eye-spot. Under surface similar to that of *chenui*, but variegated more with brown instead of grey-black. Both wings traversed by a brown longitudinal band, hindwing with three subapical ocelli, an anal one and an accessory eye-spot below the latter. From Beluchistan and Campbellpore. Rare.

affectata. **Y. affectata** *Elw. & Edw.* belongs likewise to the *baldus*-series of forms, but is larger and darker, yet in spite of the difference in the valve Elwes thinks that *affectata* may possibly be only a rainy-season form of his *similis*. The sexual spot of the ♂♂ is wanting. Assam, but very rare.

sobrina. **Y. sobrina** *Elw. & Edw.*, from the Karen Hills in Burma, resembles *marshalli* above, as also in the pattern and colouring, and is therefore evidently erected on an example belonging to the dry-season. The form of the valve, which is said to be different from those of the *baldus*-races, was decisive for the erection of the species, which still remains rare and is unknown to me in nature.

Y. similis *Elw. & Edw.* is likewise a rare species, larger than average examples of *marshalli* and without the sexual spot of the forewing. As in the ♀ of *baldus* the ocelli of both wings are also in *similis* placed in a lighter area, which is proximally bordered by a dark band. Under surface similar to *baldus*, but the sprinkling is more delicate and the subbasal dark band is absent. The valve sharply differentiated from those of the preceding species and of *baldus*. Karen Hills, to the north of Tungo in Tenasserim, from about 4—5000 ft., discovered by W. Doherty. *similis.*

Y. baldus *F.* produces two very different seasonal forms, of which that of the dry season, **marshalli** *Btlr.*, is figured on 99 d (that of the rainy period in the Palearctic part 34 b). On the upper surface the two are alike, beneath the brown-grey longitudinal band varies in breadth and there occur all gradations from examples with large eye-spots to those without a trace of ocelli. Sometimes instead of the latter there are small silver or only black dots present. I met with *marshalli* commonly in the rainless period from December to February in southern Annam, whilst I have *baldus* before me in large numbers from Tonkin, taken from June to August. Distribution: the whole of Anterior and Further India, also in my collection from Hainan, where the darkening which already commences in Tonkin examples becomes more definite, so that Hainan examples may be designated as **gallienus** *subsp. nov.* The under surface bears broader, darker brown longitudinal bands and smaller ocelli, more broadly bordered with brown. The larva of *baldus* is known, and lives on rice; it is of reddish ochre-yellow colouring with indistinct dark stripes. Pupa either dark ochre-yellow or brown or pale grey and spotted with brown. — **scota** *subsp. nov.* is a melanotic island race with dark brown under surface spotted with red-brown and very broad submarginal line on the forewing. Not common, February, March. Hong-Kong. — In **ishigakina** *Fruhst.* (99 e) the island melanism becomes still more distinctly noticeable, and is accompanied by a decrease in size. Moreover the upper surface is darker brown than in *baldus*, the bordering of the ocelli less light and the pale grey submarginal area is absent even in the ♀♀. The striation of the under surface is finer and of a deeper brown-red. Besides the intermediate form figured there is also an extreme dry-season form, **zodina** *form. nov.*, analagous to *marshalli*, but smaller and with dark black-brown ground-colouring. Formosa, Ishigaki (Japan), not rare. — In the Macromalayan region *baldus* is divided into four races: **newboldi** *Dist.*, a form darkened on both surfaces, with reduced ocelli, especially on the hindwing. The oblique stripes of the under surface are more delicate, thinner, the transverse striation more blackish than brown. Described by Distant from the rainy-season form. Perak, Malay Peninsula. — **moerus** *subsp. nov.* is the form from the lowlands of Sumatra. Larva according to Martin on the same ubiquitous species of grass as that of *Mycalesis mineus L.* This race is further removed from the *baldus*-type and produces no dry-season form, yet the ocelli are reduced, especially on the hindwing beneath. This is predominantly white-grey, the longitudinal stripes more prominent, but the brown shading slighter. An extremely common species in the plains, present on every grassy patch in the shade. The eggs are laid singly and are white-green, distinctly smaller than those of *Mycalesis* and darken as the larva develops, the central part becoming dotted with black; the larvae are at first white, but after feeding become white-green, with white head and dense whitish hairs. These hairs become less with each moult, the teeth at the anal end always longer, whilst those at the head are only indicated. The full-grown larva is somewhat yellowish, of perhaps the colour of half ripe oats and with a dark dorsal line. The larvae live high in the culms, on which they also hang for pupation. The yellow-green pupa is ornamented with fine brown stripes, more slender than all the *Mycalesis*-pupae, and has a rather pointed thoracic horn (Martin). — **selinuntius** *subsp. nov.* (99 d) inhabits Borneo and the Natuna Islands and more approaches *newboldi Dist.*, from which, however, it differs beneath in the red-brown instead of blackish striation. — **horsfieldi** *Moore* (= baldus *Snell.*) is as usual the most copiously white-marked subspecies. The forewing is indeed more broadly and densely scaled with black beneath than the Sumatran sister-race, but the hindwing must be called grey-white, with slighter brownish scaling, which in the median area is commonly entirely absent. At present I have only before me examples taken in East Java, which I there found common at 500—700 m. at the edges of the coffee-gardens. — **pasitelides** *subsp. nov.* is an interesting form from the island of Bawean, close to Java, which is easily recognizable beneath by the almost completely brown forewing, on which almost all the white ground-colour is wanting. The hindwing also is costally and basally more slightly shaded with black-grey than any Javan example; all the ocelli more distinct and bordered with finer yellow. *baldus. marshalli. gallienus. scota. ishigakina. zodina. newboldi. moerus. selinuntius. horsfieldi. pasitelides.*

Further towards the east, in the Micromalayan region, and beginning from Bali, occurs a magnificent species, which is more widely distributed than was formerly known, namely **Y. aphnius** *Godt.*, originally described from Timor, but apparently occurring in exactly the same form also on Wetter. — The furthest removed from the name-type is **caratonus** *subsp. nov.*, of which I took a ♀ on Bali in October 1895. It is distinguished by its smaller size and especially by an almost pure white foreground to the ocelli in the anal area of the hindwing. — A somewhat larger form is **saravus** *subsp. nov.*, from Lombok, which occurs there at altitudes of 600—1000 m. and is nowhere rare at the edge of the woods and on the banks of the streams which intersect the plateau of Sambalun. The anal part of the hindwing is above darkened and all the ocelli *aphnius. caratonus. saravus.*

are larger than in the Bali form. *saravus* shows a tendency to produce aberrations, as out of four ♂♂ I
leuce. possess two with the yellow bordering of the ocelli enormously developed. — **leuce** *Doh.* (99 d), described from Sumba and Sumbawa, but only received by me from the former island, bears like ~~*ningas*~~ *nyrias Fruhst.* from Celebes a strikingly pale marginal area on both wings above and differs on the underside of the hindwing from
glabrius. Lombok examples in the purer white-grey ground-colouring. — In **glabrius** *subsp. nov.*, from Flores, the foreground of the ocelli of the hindwing assumes a yellowish shading and all the ocelli are broadly ringed with
budinus. ochre-yellow. Flores; flies in November. — **budinus** *subsp. nov.* has the eye-spots of the forewing as broadly margined with dark ochre-yellow as *aphnius* and the under surface of the hindwing assumes a darker colour-
aphnius. ing than in *leuce* and *glabrius*. Alor. — **aphnius** *Godt.* (99 d), from Timor and Wetter, is the extreme form which, as may be seen from the figure, has the foreground of the ocelli on the hindwing entirely ochre-yellow. The under surface is darker, being sprinkled with black instead of white-brown as in the other branch-races. — According to Elwes and Edwards *aphnius* (*leuce*) differs from *baldus* (*horsfieldi*) in the form of the valve, which bears a lamella on the concave innerside near the end.

argillosa. **Y. argillosa** *Snell.* is perhaps the Javan race of *aphnius*. Collected by Dr. Piepers in West Java and differing from *aphnius* in the absence of the orange part round the ocelli of the hindwing. The sexual mark on the forewing above especially developed.

argus. In Japan and on the adjacent mainland *baldus* is represented by **argus** *Btlr.*, which Elwes regards as a separate species on account of the difference in the clasping-organs. And indeed the quite different, almost rounded shape of the wings helps to confirm the separation. The species is common in Japan, occurring
evanescens. everywhere from Hakodate to Nagasaki. — As **evanescens** *Btlr.* a dry-season aberration has been described
pratti. in which the eye-spots are reduced to very minute rings. From Nikko, Japan. — **pratti** *Elwes*, from Ichang,
hyampeia. bears above a conspicuous marginal band, which is sharply defined proximally. — **hyampeia** *subsp. nov.* (99 e) is the local race from Ussuri and probably also from Amur, and stands in about the same relation to *argus* as *ishigakina Fruhst.* to *baldus*. Size smaller, ocelli above less brightly pupilled with white, under surface predominantly black instead of white-grey, the eye-spots much smaller.

stellera. **Y. stellera** *Eschsch.* replaces *baldus* on the Philippines and differs from it in having the apical ocelli of the forewing more oblong and margined with darker ochre-yellow, the under surface more whitish, traversed by sharper brown bands, and the bordering of the eye-spots on both wings again darker yellow. Were it not that Elwes and Edwards regard the two species as separate on account of the genitalia, I should unhesitatingly unite them. On all the Philippine Islands from Luzon onwards. Local races occur, but nothing
galeria. is known of them for want of material for comparison. — **galeria** *subsp. nov.* is a smaller race than *stellera* from Bazilan, with the eye-spots on the upper surface naturally smaller and with darker brown-grey under surface, in which the reduced ocelli and very broad, brown longitudinal bands are especially striking. Pala-
sepyra. wan. — In **sepyra** *Hew.* (99 e) the darkening has progressed still further and the under surface is distinguished by the reddish ochre-yellow bordering of the ocelli on the forewing, recalling *aphnius Godt.* (99 d), although not so strongly expressed. On the upper surface of the hindwing there are in the ♂ three, in the ♀ four moderately strongly bordered eye-spots. Batjan, Halmaheira, Ternate, common. Indications of localities such as Celebes, Borneo, Java, which are found in literature, rest on errors or a confusion with other species.

nynias. On Celebes *baldus* is represented by **Y. nynias** *spec. nov.* (99 ♂♂ misprinted *ningas*), a strikingly small species (otherwise Celebes always produces the largest forms of the collective species), noticeable on the upper surface for the contrast of the light grey submarginal area, which is divided by a very broad dark brown band from the dense and dusky brown basal area. The ocellus of the forewing, compared with that of *sepyra*, is laterally strongly compressed, the bands on the under surface are in examples from South Celebes sometimes more indistinct than on the figure, and in the dry-season form, which I collected in the neighbourhood of Macassar, the ground-colour becomes grey and the eye-spots are reduced. Common in North Celebes at Toli-
aretas. Toli, November, December. — **aretas** *subsp. nov.* bears in the ♀ again almost circular ocelli on the forewing, which only in the ♂ retain their oblong shape. The upper surface of both sexes is darker than in *nynias*, uniform brown without the distal lighter part. The under surface lighter grey, without brown-yellow transverse striation, the longitudinal bands less pronounced than in the Celebes race. Island of Saleyer, taken by me in March 1896.

gadames. **Y. gadames** *spec. nov.* approaches *stellera Eschsch.* above, except that the two anal ocelli of the hindwing are essentially smaller. The under surface recalls *fasciata Hew.* from Borneo, but the apical ocellus of the forewing is essentially narrower than in *nynias*, the irroration on the forewing more yellowish than grey, as in *fasciata* and *stellera*, but the arrangements of the eye-spots on the hindwing otherwise as in *fasciata*. Bangkai, type in coll. Staudinger at the Berlin Museum.

nareda. With **Y. nareda** *Koll.* (99 g), already discussed in vol. 1, p. 92, begins a group of interesting species which are all distinguished by a double eye-spot on the underside of the hindwing, not accompanied by anal accessory eye-spots. *nareda* is nowhere rare in the West Himalayas; it is said to fly from May to October

and to reach an altitude of 2500 m. in the Kumaon Himalayas. Valve short, broad, at the apex a simple black spine.

Y. newara *Moore* closely approximates to the preceding, the submarginal band of the under surface is more uniform in breadth, and the striation somewhat more compact and less regular. East Himalayas, from Nepal and Sikkim to Assam, from 1000—1500 m. Valve narrow, its apex flattened and finely dentate. — As **sarcaposa** *subsp. nov.* the Burmese form is here separated, which is smaller and beneath lighter grey than large series of Sikkim and Assam examples. Ocelli with broader and lighter yellow bordering. Collected by me in May at Tungo, Tenasserim, at elevations of about 1000 m., but distributed northwards as far as the border of Yunnan. *newara.* *sarcaposa.*

Y. chinensis *Leech* (vol. 1, p. 92, 34 b) is larger than the preceding and would without hesitation have been treated as a geographical race of *nareda* if Elwes and Edwards had not established its specific rank on the ground of the constant difference of the valve, tested on 4 examples. Valve bi-lobed, proximally armed with 5 teeth. Collected at Kiu-Kiang in May, at Chang-Yang in August, made known by Leech. *chinensis.*

Y. perfecta *Leech* is a species recognizable by the larger anal ocelli on the hindwing above, the straight-edged foreground of the apical eye-spots on the underside of the forewing and the cospicuous, almost white median area of the hindwing. Central and West China. — **akragas** *subsp. nov.*, somewhat larger, the ocellus of the forewing narrower. Under surface essentially darker, with the exception of the very narrow median area, which is basally widened and distally almost pure white. All the eye-spots of the hindwing somewhat smaller than in *perfecta*. Formosa, very rare. *perfecta.* *akragas.*

Y. sordida Elw. & Edw. belongs near *perfecta*, already discussed vol. 1, p. 92. Kiu-Kiang.

Y. lycus *Nicév.* has narrower wings, but the same arrangement of the eye-spots as *nareda* except that the anal ocelli on the underside of the hindwing are smaller. Under surface dark grey, with unusually fine striation. The only locality yet known is the Khasia Hills in Assam, where it occurs from March to July at about 1500 m. It flies somewhat more swiftly than *newara*, prefers open places and is not very rare, but hardly ever finds its way into German collections and I possess only 1 ♂. *lycus.*

Y. watsoni *Moore* apparently replaces *lycus* in Burma and might be taken for a mere local form if the valve did not differ strikingly from the simple, very slender *lycus*-valve in having a subapical, broad, proximally comb-shaped appendage. The rainy-season form resembles that of *nareda* and the striation on the under surface is more scattered. The ocelli are more uniform than in *lycus*, the dry-season form shows very broad brown bands on a light grey ground. Burma, from Tongu to the border of Yunnan. *watsoni.*

In East Asia in place of *nareda* and *newara* occurs **Y. motschulskyi** *Mén.*, a species with large eye-spots, which has been already dealt with in the Palearctic part (vol. 1, p. 92). I took the species on the island of Tsushima, end of September to beginning of October. — **amphitea** *Mén.* is a form from Korea with the sexual spot on the forewing reduced, whilst in **ganus** *subsp. nov.*, from Tsintau and probably also Ichang, it is especially distinctly developed. *ganus* is inferior in size to Japanese specimens and the ocelli are correspondingly reduced. The under surface bears the same relation to *motschulskyi* as *sarcaposa Fruhst.* to *newara Moore*, with its light grey ground-colour and fine striation. *motschulskyi.* *amphitea.* *ganus.*

Y. obscura *Elw. & Edw.*, from Korea, nearly approaches the Japanese race in colouring and pattern, but the valve is of widely different form, in *motschulskyi* having the teeth at the distal end, whilst *obscura* bears them at the dorsal, proximal part in almost twice as long a row. *obscura.*

Y. multistriata *Btlr.* (= posticalis *Mats.*) (99 g) bears the dentition of the valve also at the distal end, but its form is simpler and more slender, so that Elwes and Edwards are probably also right here in advocating its specific separation from the Japanese form. Beneath *multistriata* differs from *motschulskyi* in the more compact and darker brown shading, more condensed into single patches resp. spots. Formosa, not rarely ascending to about 4000 ft. — **imitans** *Elw. & Edw.*, from Hainan, differs above in the lighter distal area of the forewing and on the under surface in the reduced brown striation on a very light, nearly white ground. The margining of the ocelli is also paler and of a finer yellow. *multistriata.* *imitans.*

Y. praenubila Leech (vol. 1, p. 92, pl. 34 c), a specially large species, in many ways recalls the species of the next group. Central and West China, from May to August, does not belong to the Indo-Australian fauna.

Methora Group.

With **Y. methora** begins a series of species which far surpass their congeners in size, reaching or exceeding that of the European *Pararge*. — Two local forms of *methora* are known: **methora** *Hew.* (99 g), erected *methora.*

from the rainy-season form, nowhere rare in Assam, but in Sikkim extremely sparsely represented, and there observed at about 1000 m. The Assam specimens, and also those of the dry-season form, are essentially darker than Sikkim examples and have larger eye-spots. As the dry-season form has not yet been christened, I would *gela.* propose the name **gela** *form. nov.* for. it. It coincides with fig. 99 g. The upper surface may be described as vandyke brown. The hindwing bears always two anal ocelli, the ♀ also an apical ocellus on the upper surface. In the ♀ of the form *gela* there is sometimes further an apical accessory eye-spot, also in one ♀ the anal ocelli are diffuse and tear-shaped. The rainy-season form flies in August in Sikkim and Bhotan, whilst *gela*, the *persimilis.* generation of the cold season, was observed in February and March. — **persimilis** *Elw. & Edw.* bears no sexual stripe on the forewing above and the anal ocelli of the hindwing are not as in *methora* and *gela*, but only ornamented with two white pupils. From Mao, Manipur, from elevations of 7000 ft. Rare.

dohertyi. **Y. dohertyi** *Moore* closely approximates to *methora*, so that it should perhaps be treated as a local race of this, for even the trifling deviations in the distal part of the valve may just as well be individual as due to its geographical separation from the centre of the collective species. But as *dohertyi* is unknown to me in nature I accept the opinion of Bingham and Elwes as to its status. ♂ with more prominent sexual spot on the forewing. Upper surface paler brown, the anal ocellus of the hindwing divided. Under surface whitish with small, short brown stripes, the longitudinal bands indistinct. Eye-spots of the under surface with very broad yellow iris. Localities: Upper Burma and Pegu, at about 2000 ft.

savara. **Y. savara** *Gr.-Sm.* bears likewise a distinct grey androconia-patch with dull gloss on the forewing. The upper surface is lighter brown than even in *gela* and beneath both wings are traversed by two brown longitudinal bands. The type came from Upper Tenasserim, other examples were found at Tungo in March and April and Doherty afterwards discovered this rare species in Pegu at about 600 m., likewise in March-April. *tonkiniana.* — **tonkiniana** *subsp. nov.* (99 f) differs from *savara* in the usual darker colouring of Tonkin butterflies, the consequently much widened longitudinal bands on the underside of the wings, and the larger ocelli, which are almost circular instead of oval and have the light yellow bordering still more extended. Rare in Tonkin, very local, collected by me only at Chiem-Hoa, July-August, at about 500 m.

conjuncta. **Y. conjuncta** *Leech* (vol. 1, p. 93, pl. 34 b) has the same arrangement of the anal ocelli on the hindwing as *savara*, but the ground-colour is almost black-brown and the apical eye-spot of the forewing essentially smaller. *formosana.* Central and West China, common. — **formosana** *Fruhst.* (= tappana *Mats.*) (99 f) is smaller than *conjuncta*, the eye-spots on the forewing are also considerably smaller than in *methora* from Assam and *conjuncta*, the under surface of the wings lighter grey and the ocelli more narrowly bordered with dark yellow. Not rare on Formosa, ascending to 4000 ft.

Y. sakra I consider the most striking species of the genus and the easiest to determine; it is indeed the only one which has the ground-colour on the underside of both wings yellow-brown and which bears two large ocelli, but surrounded by a single border, in the costal area of the hindwing. Three branch-races are known: *nikaea.* **nikaea** *Moore* (vol. 1, p. 93, pl. 34 e) is the form of the western Himalayas, which is paler beneath and also *sakra.* of smaller size and is very common particularly at the higher elevations from 3—11 000 ft. — **sakra** *Moore* comes in every consignment from Sikkim and Bhotan, where it must be regarded as by far the commonest species of the genus from 2000—8000 ft. Only the rainy-season form is known, which from March to November *austeni.* is a typical butterfly of the highroads, enlivening the grassy and bushy waysides. — **austeni** *Moore* is if anything somewhat larger than *sakra* from Sikkim, the ♀ considerably darker, without the fine yellow-brown marbling on the upper surface. Moreover the under surface no longer shows the beautiful colouring of *sakra*, but is inclined rather to grey-brown, yet the ocelli are somewhat larger and more uniform. Assam, Burma, not *matinia.* common. — **matinia** *subsp. nov.* surpasses *sakra* in size and the under surface, particularly that of the hindwing, is lighter, nearly whitish grey. Common in North-West India.

Y. methorina Oberth. (vol. 1, p. 93, 34 e) and *medusa Leech*, from West China, belong near *methora* and *sakra* and are discussed in the Palearctic part.

In the Philippine Archipelago, on Celebes and in Macromalayana we meet with a group of three or *pandocus.* four species likewise distinguished by their size, which closely approximate to *methora* and *conjuncta*. **Y. pandocus** is the best-known representative, and inhabits the whole of the above region, but nowhere passes over to the continent with the exception of the Malay Peninsula, which, as has already been repeatedly mentioned, produces a thoroughly insular fauna on account of its maritime climate. In the clasping-organs the species is distinguished by having by far the slenderest and most pointed valve of all the *Ypthima* examined by Elwes and Edwards. *corticaria.* — **corticaria** *Btlr.*, described from Malacca, and also occurring in an almost identical form on Sumatra and the Batu Islands, is above somewhat lighter than the figured *sertorius Fruhst.* (99 e), which also differs beneath in the dark smoke-brown hatching and broader submarginal longitudinal band on the forewing, as well as in having *moenus.* the distal area of the hindwing more broadly shaded with brown. — **moenus** *subsp. nov.*, from the Natuna Islands, bears on the forewing a much larger apical ocellus, which beneath is surrounded by a lighter area than

in *corticaria*. — **naerius** *subsp. nov.* is a small race from Nias, with reduced ocelli and much lighter beneath, somewhat recalling **alada** *form. nov.*, which I have before me in both sexes from the Battaker Plateau, North-East Sumatra, from about 1000 m.; in this the hindwing is almost entirely washed-out white-grey, showing distinctly a dry-season coloration, and is ornamented with minute eye-spots. — **pandocus** *Moore* (99 f). On the figure the under surface is not quite correctly reproduced, wanting the grey-white median shade. The figure represents the dark mountain and rainy-season form, which is met with especially at Mt. Gedé and on the Plateau of Pengalengan in neglected coffee-gardens, often in hundreds, at altitudes of 12—1500 m. Deeper in the valleys and in the almost rainless season flies a much lighter form, **dyma** *form. nov.*, the under surface of which is tinged with grey-brown, without black admixture, the whitish patch in the median area of the hindwing more distinctly sprinkled with yellowish. — **andokides** *subsp. nov.* is analogous to the form *dyma*, but smaller; very common in East Java at about 500 m. — **sertorius** *subsp. nov.* (99 e), in which the ♀ bears also above a larger apical eye-spot than even the Java form. Particularly compared with *corticaria Btlr.* from Perak, *sertorius* is seen to be larger and with more extended black-brown shading on the under surface. The differences of the ♀ of *sertorius* from that of *pandocus* may be seen by a comparison of the figures. North and South-East Borneo, Pontianak, Natuna Islands. — **jamaeus** *subsp. nov.* is an interesting race from the small Sulu Island of Banguey to the north of Borneo, and is smaller than *calanus* (99 e), but much darker and with the ocelli on the hindwing beneath scarcely half as large. Type in coll. Staudinger. — **aquillius** *subsp. nov.* is the rare race from Palawan, which forms a transition from the Banguey form to *calanus*, the ocelli being above intermediate between those of these two island representatives of the collective species. The apical ocellus of the forewing only with inappreciable yellow bordering. Upperside of the hindwing sometimes dusted with white. Type in coll. Staudinger. — **calanus** *subsp. nov.* (99 e) on the whole approaches *sempera Fldr.* from Luzon, from which, however, it is easy to distinguish by the extended white-grey distal and median part of the hindwing beneath. Moreover all the ocelli on the underside are surrounded by a light yellow border. Jolo Islands. — **chaboras** *subsp. nov.* is a geographical branch inferior in size to *calanus* and *sempera*, which inhabits Bazilan, to the south-west of Mindanao, and is not rare there in February and March. In the ♀, as in that of *sakra*, a fine, delicate, brown-yellow marbling is noticeable above and the eye-spots are relatively large, bordered with light ochre-yellow. The under surface differs considerably from that of *calanus* in having the brown shading condensed into rather large striae and patches. Judging from a figure of Semper's the Mindanao race does not differ materially from *chaboras*. — **sempera** *Fldr.* inhabits Luzon and some of the neighbouring islands, where it flies all the year round, especially from April to July and then again from October to January. According to the examples in my collection the under surface of the Luzon ♂♂ is more uniformly grey and especially on the hindwing darker than in *chaboras* from Bazilan and Mindanao. Also the submarginal band of the forewing is much widened and the distal brown border of the hindwing extends more deeply towards the middle of the wing. — In vivid contrast to the small race from the Philippines, stand the *pandocus*-branches from Celebes, of which that from the south, **loryma** *Hew.*, was given in Elwes' Monograph as synonymous with *celebensis Rothsch.* (99 g), from which it is at once distinguishable by the presence of the apical ocellus of the forewing on the upperside also and beneath by its rounded instead of oblong shape. Moreover in *celebensis* the two eye-spots on the under surface of the hindwing are either of equal size or the apical ocellus is even larger than the anal one. In *loryma* on the contrary the posterior ocellus invariably exceeds the anterior in extent. Compared with *pandocus* and *sertorius*, *loryma* bears larger ocelli on the hindwing above. *loryma* is common in the south of the island, from the bed of the Maros River up to elevations of 1500 m. As **anana** *subsp. nov.* (99 f) I designated at one time a form from East Celebes with smaller eyes beneath, as I assumed that *celebensis* should be united with *pandocus*. As a matter of fact, however, *anana* is probably scarcely more than an intermediate form. — **macrianus** *subsp. nov.*, from the Minahassa, however, differs considerably from *loryma*; ♀ a third larger, the foreground of the apical eye-spots lighter brown, the under surface in both sexes similar to that of the mountain form of *pandocus*, with an extended grey-white basal and median area on the hindwing, but sparsely scaled with brown. All the ocelli are moreover ringed with lighter yellow. North Celebes, apparently rare. — **kalelonda** *Westw.* is a strongly darkened race from the island of Talisse, near the northern point of Celebes.

naerius. *alada.* *pandocus.* *dyma.* *andokides.* *sertorius.* *jamaeus.* *aquillius.* *calanus.* *chaboras.* *sempera.* *loryma.* *anana.* *macrianus.* *kalelonda.*

Y. celebensis *Rothsch.* (99 g, wrongly printed *lorymna*), in addition to the characters mentioned above, also differs in the presence of a second median light brown longitudinal band, which stands out especially distinctly on the anterior part of the hindwing in the ♀♀. The submarginal band on both wings above and beneath is also twice as broad as in *macrianus*. Common in the lowlands, taken by me at Toli-Toli in the north of Celebes, November-December, whilst in southern Celebes I not infrequently met with the typical form, with the under surface somewhat lighter grey, in November.

celebensis.

Y. ancus *spec. nov.* (99 g) is the third species of the *pandocus* group which we meet with in Celebes. It is a pronounced mountain form, and was taken by me at the Peak of Bonthain together with *pandocus* and

ancus.

celebensis and at the same time. The upper surface differs from that of *loryma* in the uniform black-brown, which in the distal area of both wings is slightly inclined to red-brown. On the under surface, which is very well depicted on 99 g, all the yellow shading is absent, the eye-spots are rounder, bordered with more pronounced dark orange-yellow. The foreground of the ocelli somewhat paler than the rest of the ground-colour.

nigricans. **Y. nigricans** *Snell.*, previously known in a few examples from western Java, was also found by me in the east of the island at about 500 m. above sea-level. In colouring it is above very similar to *ancus*, but the under surface is different, more approaching *pandocus*, in the presence of a brown-grey tone on the forewing and a whitish median area on the hindwing. The hindwing is always more broadly margined with darker brown than in *pandocus*, the anal ocellus compared with the subapical relatively larger and all the eye-spots on the whole more uniform. — In the Zuider Mountains to the south of Malang occurs also a dry-season form (**phasis** *form. nov.*) with the ocelli on the hindwing beneath reduced to mere dots.

phasis.

Y. iris Leech (vol. 1, pl. 34 d) with *dromonides Oberth.* (vol. 1, pl. 34 d), *beautei Oberth.* (vol. 1, pl. 34 c) and *ciris Leech* (vol. 1, pl. 34 d) form a small group of Eastern Palearctic species with very obliquely placed oval, bi-pupilled ocellus on the forewing and two to three subanal ocelli, as well as an apical eye-spot on the forewing. All inhabit eastern China, partly at elevations of 5—8000 ft. and are fully dealt with in vol. 1 (p. 92—93).

clinoides. **Y. clinoides** *Oberth.* is a form or species unknown to me in nature, which should be placed near *iris Leech* and is characterized by the absence of the anal ocelli on the hindwing above. Described from Yunnan, collected by missionaries at Tsekou.

dromon. **Y. dromon** *Oberth.* differs from *iris Leech* in the smaller eye-spots, which on the under surface are nearly obsolete. Yunnan, Tsekou.

Y. megalomma Btlr. (vol. 1, p. 92, pl. 34 c) belongs to a small south-east Palearctic group, which embraces but few species, with large rounded eye-spots on the forewing and a medium sized ocellus on the hindwing above, but entirely without eye-spots on the hindwing beneath. The species was discovered at Ningpo, where it flies in April, and afterwards also in Chang-yang, Central China, as well as West China, where it ascends to 5000 ft.

megalia. **Y. megalia** *Nicév.*, discovered in the upper Shan States near the borders of China, where it likewise flies in April, is about the size of *sakra Moore* and has the hatching beneath quite as fine. But on the upper surface it approaches *megalomma*, except that the ocellus is oblong. The hindwing is beneath brown, with slight indication of a subbasal and median white-grey band and entirely without eye-spots.

Y. insolita Leech (vol. 1, p. 92, pl. 34 d) is extremely rare in West China, flying in June at elevations of 5000 ft. Under surface white-grey with brown spar-shaped band and traces of small eye-spots.

abnormis. **Y. abnormis** *Shelford*, described from a ♀, belongs in this group unless it is an aberrant form. Upper surface without ocellus. Under surface pale brown with dark, somewhat reddish stripes, which divide off three areas. Hindwing with five irregular and somewhat indistinct bands, likewise without eye-spots. Abdominal margin of the hindwing deeply excised and the distal margin slightly undulate. 57 mm. expanse. From Sarawak, but very rare. Type in the Sarawak Museum.

2. Genus: **Xois** *Hew.*

This small Australian genus is closely allied to *Ypthima* and only differs from it in the distinctly bifurcate precostal vein of the hindwing and the shorter terminal joint of the palpi. Only two certain species known, which inhabit the Fiji Islands. They are small delicate butterflies of whitish colouring, with a large eye-spot, bi-pupilled with white, in the darker apex. On the under surface the wings are finely striated, the hindwing always without ocelli.

sesara. **X. sesara** *Hew.* (= diophthalma *Prittw.*) (99 g) is a not very rare species, with the under surface in the ♂ dark, in the ♀ somewhat lighter ochre-yellow. Concerning the habits nothing is known. Viti Levu.

argentina. **X. argentina** *Prittw.* is said to come from Samoa.

fulvida. **X. fulvida** *Btlr.*, with which *X. vitiensis Fruhst.* (93 f) is probably identical, differs according to my types in having the forewing broadly margined with black above and a moderately broad black distal margin to the hindwing. The margining of the forewing shows through beneath, but the hindwing bears only a narrow, fine, brownish distal border. On the forewing only the basal and apical parts are suffused with yellowish, the median area remaining pure white. The hatching on the hindwing is more slender than in *sesara*. Apparently very rare. Both sexes in coll. Fruhstorfer. Viti Levu.

3. Genus: **Acrophthalmia** *Fldr.*

In size approximating to the preceding genus and also embracing but few species, but the butterflies differ structurally in the point of origin of the lower radial, which arises directly from the subcostal, in consequence of which the latter and the upper radial are placed on a common stalk. The upper radial strongly bent at its base. Lower radial partially united with the upper median. At this place the ♂♂ possess a membranous pouch, which is continued to the distal margin as a fold in the membrane. This fold is wanting in the ♀♀, and hence their lower discocellular is more simply developed and only shortly angled. Forewing with two subcostal veins before the end of the cell, a small oblique middle discocellular and a large angled lower one, which as in *Euploea* and some other *Satyrid*-genera emits a blind vein proximally. *Acrophthalmia* differs from *Ypthima* and *Xois* in not having the median and submedian swollen, only the costal being inflated. But few species, small, delicate butterflies of predominantly white colouring, which all bear an ocellus on the underside. Their area of distribution is the Philippines, from whence they have probably reached Celebes and the Moluccas. One continental species hitherto united with it is shown under the next genus (*Pharia*) not to belong here.

A. artemis is the only certain species of the genus and is distributed in about 5 branch-races over the Philippines and the neighbouring islands. — **leuce** *Fldr.* (90 e), found by me in northern Celebes near Toli- *leuce.*
Toli, November—December, in the lower scrub at the edges of the woods, where they fly like *Ypthima* and rest on twigs and leaves. Upper surface rather dark grey-brown, leaving a broad whitish median area on each wing. — **lacrima** *Fruhst.* (= chionides *Nicév.*), somewhat smaller than *leuce*, is above so broadly grey-brown *lacrima.*
that only a very narrow white median area remains. On the underside of the hindwing the brown median zigzag line is absent, which is distinctly shown on the figure of *leuce*. Sula Mangoli, discovered by W. Doherty October-November. — **chione** *Fldr.* (93 f), from the North Moluccas, is essentially larger than *leuce*, but simi- *chione.*
larly coloured. The distal border of both wings, however, is deeper brown, the median area more extended and purer white, ocelli of the under surface and their accessory eye-spot somewhat more distinct than in *leuce*. In my collection from Halmaheira and Batjan, according to Hewitson also on Morty or Morotai, Oberthür says on Andai, New Guinea. The latter locality still requires confirmation. According to Pagenstecher it has been found by Kükenthal on the Uliassers *). — **artemis** *Fldr.* has the largest white median area of all the Phi- *artemis.*
lippine races; according to Semper the underside has the ocelli somewhat differently pupilled and the zigzag line removed further from the eye-spots. Apparently not very common on Luzon. Flies April to July. — **misarte** *Semp.* *misarte.*
inhabits Mindoro and is a darkened island race of the preceding, with the white discal area of both wings reduced, light grey bordering and the median line on the underside of the hindwing removed somewhat nearer still to the base. Flies in December, rare. — **ochine** *Semp.*, from Samar, Leyte and Panaon, agrees *ochine.*
above with *chione Fldr.* from the Moluccas and also bears occasionally a green gloss, which is said to occur in *chione*. The submarginal line on the under surface somewhat more undulate than in *chione*. — **machares** *subsp. nov.* differs from *artemis* in having a considerably broader dark brown border on the upper *machares.*
surface and beneath in the more uniform and more extended white area, which is anteriorly rounded, particularly towards the costal region of the forewing. Bazilan; February, March; collected by W. Doherty. — **leto** *leto.*
Semp., from Bohol, is almost entitled to specific rank, but apparently only differs above in having the forewing filled up with yellow. On the hindwing the yellow tinge only extends on to the transcellular region. Likewise rare. Flies in December and January.

4. Genus: **Pharia** *gen. nov.*

The single species of this hitherto unrecognized genus inhabits western China and was discovered by me in Tonkin. *Pharia*, indeed, in common with *Acrophtalmia* has only the costal inflated, the median and submedian showing no swelling at all; yet it is so sharply separated from it in neuration as is the case in few allied genera. In the first place the scent-fold on the hindwing is wanting in the ♂♂, and the the middle and lower discocellular of the short, broad cell of the hindwing are of normal, simplest structure, the middle discocellular somewhat shorter than the lower. On the forewing the lower discocellular is not incurved, but runs obliquely distad as in *Xois*.

Ph. thalia *Leech* (vol. 1, p. 80, pl. 29 a). A single example of this butterfly, hitherto only known from Omi *thalia.*
Shan, flying in July, was detected by me from the environs of Langson, North Tonkin, June to July.

5. Genus: **Hypocysta** *Westw.*

A well defined genus, which divides into two principal groups, easy to distinguish especially by the colouring, namely the Australian, grouped round *irius*, which Fabricius already knew, of the typical Australian

*) This locality is most probably a mistake for Batjan or Ternate.

brown sand-colour (which is also repeated in other genera, e. g. *Heteronympha*), and those which inhabit New Guinea, with predominantly black and white or dark brown colouring.

Superficially the *Hypocysta*-species resemble *Acrophthalmia*, from which, however, they differ in the simple neuration of the hindwing, moreover the three principal veins of the forewing are inflated. The fore-legs of the ♂♂ small and delicate, but not so much aborted as in *Ypthima*. A series of species are already known and on every large expedition new ones are still discovered. All are small delicate butterflies with a large eye-spot on the hindwing, more rarely also with one on the forewing. The genus is exclusively Australian and Papuan and already disappears on the eastern satellite-islands of New Guinea.

irius. **H. irius** *F.* resembles in habitus the figured *antirius* (93 d) and recalls the Palearctic *Coenonympha pamphilus L.*: it is common in Queensland, where it occurs everywhere from Brisbane to Cape York. Upper surface yellowish, hindwing with two small eye-spots, which are smaller on the grey under surface and are proximally bordered by a white longitudinal band.

antirius. **H. antirius** *Btlr.* (93 b) is little larger than *irius*, without the black distal border which *irius* bears on both wings above, and beneath without the proximal white longitudinal band in the median area of the hindwing. North-West Australia, Port Darwin.

adiante. **H. adiante** *Hbn.*, unknown to me in nature, likewise inhabits North-West Australia, but extends in *undulata.* addition from Sydney to the extreme north of Queensland. **undulata** *Btlr.* is a seasonal form without essential differences.

metirius. **H. metirius** *Btlr.*, an interesting species with extended ochre-coloured area on the hindwing above, forewing grey-brown. The two eye-spots on the underside of the hindwing are separated by a narrow yellowish band. Common, distributed from Sydney to Cairns.

pseudirius. **H. pseudirius** *Btlr.* differs from the preceding species in having an ochre-coloured patch on the forewing, *epirius.* which is also slightly indicated beneath. Scattered over as wide an area as the preceding. **epirius** *Btlr.* is again a seasonal form of the collective species, which is parhaps split up into several races that have not yet been studied.

euphemia. **H. euphemia** *Westw.* (93 d), mostly somewhat lighter than on the figure, may be easily recognized by a large ocellus on the forewing, which is placed between the medians, and a small subapical eye-spot before the apex of the forewing. Both are reproduced beneath. Under surface of the hindwing yellow-grey, with fine median longitudinal stripe and a grey connecting shade between the ocelli, which are of almost equal size. Common near Sydney.

H. isis *spec. nov.* inhabits the main island of New Guinea and also extends on to some of its satellite-islands, flies apparently all the year round, but occurs most commonly from November to April and inhabits the woods in the lowlands, apparently without ascending to such considerable elevations as the preceding spe-
isis. cies. — **isis** *Fruhst.* (93 d) is to be met with in the western parts of German New Guinea. The ♀♀, however, are rare and may be distinguished from the ♂♂ by the more rounded wings and the white median area of the
pelagia. forewing, which is essentially broader than in *osyris*. — **pelagia** *subsp. nov.* flies in Humboldt Bay, Dutch New Guinea, where it was discovered by Doherty September-October 1882. The form is easy to recognize by having the forewing somewhat more darkened than in *isis* and the white band on the hindwing scarcely half
isias. as broad. — **isias** *subsp. nov.* is a very interesting race from south-western Dutch New Guinea with entirely black-grey forewing and very broad white area on the hindwing, reaching to the ocelli. Type in the Tring Museum;
senona. Kapaur, discovered by Doherty. — **senona** *subsp. nov.* is a form which closely approaches *isis*, but in which the ♂♂ also bear a distinct white band-like median area on the forewing, similar to that of the ♀♀ only not so extended. Beneath this white area is quite as pronounced, but not more extended than in *isis* from Friedrich-Wilhelmshafen. According to Hagen common in the woods near Stephansort and Simbang from November
busiris. to April. — **busiris** *subsp. nov.* already recalls *leucomelas* (93 d), but the forewing is more slender, the anal angle more distinctly rounded and the ground-colour brown instead of black. It differs from *isis*, *senona* and *pelagia* in the entire absence of any light median shade, whilst on the other hand the ♀ shows a much more conspicuous, broader white median area on both wings than the ♀♀ of all the above races. Moreover the ocellus on the hindwing is considerably enlarged and its bordering is more prominent and lighter yellow than in the *isis* races from New Guinea. Misol, discovered by H. Kühn, collected in January.

H. osyris is distinguished by the brown-grey bordering of both wings, recalling in colour *haemonia Hew.* and *fenestrella Fruhst.* (93 d), a colouring which is not brought out successfully on the plate. The basal area of the hindwing always more or less tinged with yellowish, never so pure white as
osyris. in *isis Fruhst.* There are only a few branch-races known, of which **osyris** *Bdv.* (93 d) inhabits the Aru Islands. The ♂♂ show no white median area on the forewing above, but in its place a scarcely appreciably lighter patch. The black eye-spots of the hindwing are more narrowly ringed with yellow than in the ♀. Under surface of the hindwing with a metallic, silvery submarginal band and a similar border to the

small apical eye-spot and to the anal one, which is twice as large. — **nephthys** *subsp. nov.* was discovered by Meek in the year 1899 at Milne Bay and in November to March 1904—5 on the Aroa River. Smaller than *osyris*, it naturally shows also smaller ocelli on the hindwing, with scarcely appreciable dark brown bordering. The white basal area of the hindwing is almost quadrate, does not extend beyond the cell, and is shaded with yellowish grey. On the underside of the forewing the white median area is much restricted and the distal more extended. — **frenus** *subsp. nov.* approaches *osyris* in its larger size and is distinguished from *nephthys* by the somewhat more extended white basal area of the hindwing above, and beneath by broader grey-black and metallic bands. British New Guinea at altitudes of over 2000 m. November to February. *nephthys.* *frenus.*

H. hathor *spec. nov.* approximates in both sexes to *serapis* from Dorey, but is easy to distinguish from this and especially also from *isis isis* by the very broad but short white area, which already at the cell-wall of the hindwing gives place to the ground-colour. Anal ocelli of the hindwing narrower than in *isis*. British New Guinea, January and February, collected by Meek. *hathor.*

H. aroa *Beth.-Bak.* is a particularly large and striking species, recognizable by the very broad, pure white area of the forewing and the distally pointed, dazzling white area of the hindwing, which extends far beyond the cell. Both sexes differ from all the other known *Hypocysta* in the entire absence of the yellowish bordering to the ocelli of the hindwing, which hence appear very narrow above. British New Guinea, from the upper Aroa River. Flies in March—April. — **serapis** *subsp. nov.* is the race from Dutch New Guinea, whose ♂ approaches that of *isis* in the yellowish instead of white patches on the forewing. ♀ with much narrower white area on both wings, on the under surface not entering the cell of the forewing, as in *aroa*. Dorey, Dutch New Guinea. *aroa.* *serapis.*

H. haemonia is only known as yet from the Aru Islands and Dutch New Guinea. Three local forms deserve mention: **fenestrella** *subsp. nov.* (93 d), from Sekar, Dutch South-West New Guinea, which differs in the lighter forewing and the narrower black, tri-pupilled ocelli of the hindwing from **haemonia** *Hew.*, from the Aru Islands, whose ♀ is only distinguished from the ♂ by the more rounded wings, and the somewhat more extended tripartite black ocelli of the hindwing and their broader yellow-brown bordering. Flies (according to Kühn) in September. — **pelusiota** *subsp. nov.* is a distinct form from Humboldt Bay, Dutch New Guinea, almost a third larger than *haemonia* ♂, with the hindwing also lighter, showing a grey-yellow basal area. ♀ with grey-white, very broad median area on both wings. Under surface with the silver bands almost twice as broad as in *haemonia*, the proximal one distinctly bordered with brown proximally also. Flies in September—October, discovered by W. Doherty. Types in the Tring Museum. *fenestrella.* *haemonia.* *pelusiota.*

H. leucomelas *R. & J.* (93 d) was placed by its authors in the genus *Platypthima*, but it seems to agree better with the other *Hypocysta* than with *ornata R. & J.*, the type of *Platypthima*, which we figure pl. 99 c. The under surface differs from all the known Papuan *Hypocysta* in the absence of any apical ocellus on the hindwing and the rounded instead of oblong anal ocellus. British New Guinea, Aroa River, rare. *leucomelas.*

6. Genus: **Argyronympha** *Math.*

The only species probably of this charming group deserves its name of „Silver Nymph" by reason of the brilliant adornment, which in the numerous island races decorates the under surface of both wings in the form of metallically glossy, beautifully undulated bands and fine streaks. The ground-colour of the upper surface varies from light yellow to black-brown in the different localities. It shares with *Hypocysta*, of which genus it is really the eastern continuation, the inflation of the three principal veins of the forewing and the absence of secondary scent-pencils on the hindwing. Cell of the forewing somewhat shorter, the recurrent spur in the cell likewise less developed. Cell of the hindwing more than a third shorter. Lower discocellular on both wings scarcely half as broad as in *Hypocysta*. Thus there are sufficient differences to establish the genus, hitherto founded on no scientific diagnosis. The species are not rare, apparently easy to catch and the coloration seems to become progressively lighter towards the east of their restricted range. Ribbe writes concerning the habits: „The representatives of this genus, which I have taken only on the Solomon Islands, are small, delicate insects, which love the dense forest and are mostly found where the ground is moistened by a fresh water spring. The butterflies rest with folded wings, so that the glitter of the metallic under surface is visible from quite a distance, sitting on the leaves of the lower shrubs at about the height of a man. Their flight is slow and heavy, a mere flutter from shrub to shrub. The scales are only loosely attached to the wings, so that but few good specimens are captured. I never found the insects common, although they are to be met with singly throughout the woods. *A. pulchra* is a very variable butterfly, for on the Shortlands Islands I took specimens which, in the colouring of the under surface, closely approach *rubianensis* and on the other hand *uleva*. *pulchra* and *rubianensis* are well defined forms, but *uleva* is only a casual dark aberration. *pulchra* is known from the Shortlands Islands (Alu, Fowi, Munia, Tauro, Tanua), North Choiseul, Bougainville and Treasury, *rubianensis* from New Georgia".

pulchra. **A. pulchra** *Math.* (93 f), described from Treasury Island, bears above a very broad black distal border on the forewing, which is only at the veins slightly relieved with yellow-brown and even there densely powdered *uleva.* with blackish. Hindwing uniform black. — **uleva** *Sm.*, judging from the figure, is a relatively large form with strongly darkened upper surface, the base of which is dark red-brown and distally less sharply bounded by the black distal border. Under surface reddish grey, the red-brown transcellular band narrower than in *pulchra.* *adustata.* From the island of Ulava, discovered by Woodford. — **adustata** *subsp. nov.* is probably the most melanotic extreme of *pulchra* known, found by Meek on Choiseul, one of the German Solomon Islands. The black marginal band covers almost the whole upper surface of the wings, only leaving a narrow dark smoke-brown basal area. *argentaria.* Hindwing also in the ♀ almost entirely black, under surface whitish grey. Type in the Tring Museum. — **argentaria** *subsp. nov.* from Isabel, in the German Solomons, bears already an extended light ochre-yellow basal area on both wings, but is beneath dusted with darker grey than *adustata*, and the submarginal band of the fore- *denya.* wing and the yellow patches of the hindwing are lighter. Type in the Tring Museum. — **denya** *subsp. nov.* was discovered by Ribbe on the Shortlands Islands; it differs from *argentaria* in the lighter brown basal area of the *vella.* forewing, darker grey dusting and paler yellow bands on the under surface. — **vella** *subsp. nov.* is the lightest extreme of the species, the dark leather-brown basal area considerably widened, filling up the whole cell, under surface essentially different, basal region on the forewing dark ochre-yellow instead of grey, hindwing lighter. The metallic decoration of the hindwing blue instead of silvery, both the black and the yellow spotting considerably reduced. Flies in February, Vella-Lavella, taken by Meek. Type in the Tring Museum. — The further *rubianensis.* the locality lies towards the east, the lighter become the forms, thus **rubianensis** *Sm.* considerably surpasses *vella* in the extent and lightness of the yellowish basal area of the forewing, whilst the underside of the hind- *rendova.* wing is coloured similarly to *pulchra*, that of the forewing like *vella.* Rubiana. — **rendova** *subsp. nov.* inhabits Rendova and shows a broader black distal margin on the hindwing above, darker and more yellowish grey *guizona.* proximal half of the hindwing beneath. Flies in February. — **guizona** *subsp. nov.* is above more reddish and still more broadly suffused with yellow than *rendova* and *rubianensis*, the median part of the forewing beneath darker red-brown, the hindwing basally whitish grey. Island of Guizo, November. Type in the Tring Museum.

ugiensis. **A. ugiensis** *Math.*, of which the specific rank still appears doubtful, differs from *pulchra* in the absence of the black margining of the hindwing above and of the yellow and the proximal silver band on the forewing *yanuta.* beneath. Island of Ugi, discovered by its author. — **yanuta** *subsp. nov.* is the form from the eastern British Solomon Island San Christoval, collected there in April by Meek. Under surface of the forewing reddish ochre-yellow. Hindwing grey-yellow with reddish yellow discal band. The anal silvery spot of the hindwing distally only light yellow, but not bordered with black as in all the *pulchra*-races, all the brown stripes and patches of *pulchra* light yellow.

7. Genus: **Erycinidia** *R. & J.*

Neuration according to the authors of the genus similar to that of *Hypocysta.* The upper median somewhat nearer to the lower radial than to the second median. Hindwing produced into a long lobe, somewhat as in *Dodona* and the South American *Corades.* Also approaching *Lamprolenis* in the shape of the hindwing. Eyes naked. Only ♂♂ of one species known as yet, but further allies may be looked for from German and Dutch New Guinea.

gracilis. **E. gracilis** *R. & J.* (99 c), a noteworthy species, recalling in the shape of the wings Indian Erycinids and even the South American *Corades*, whilst the markings of the under surface are somewhat suggestive of *Lethe* (*Zophoëssa*). Under surface dark brown with violet-grey patches. On the cell of the forewing a short, broad yellowish white band, further a yellowish submarginal stripe, which traverses the entire wing. Apex with three small round ocelli. Hindwing with a dentate blackish subbasal line, a somewhat straighter median band and six yellowish-black-pupilled ocelli. British New Guinea, known from altitudes of 2000 m. November to February.

8. Genus: **Pieridopsis** *R. & J.*

We are indebted also to the „leading entomologists of Europe" for our knowledge of this noteworthy genus, which through their kindness is here figured for the first time. Wings obtuse, the structure in general analogous to that of *Hypocysta*, but the cell of both wings essentially shorter. Upper discocellular of the forewing angled, lower radial arising below this angle. Hindwing triangular, the second median ending in a broad lobe, costal margin long. Eyes naked. Easy to distinguish from *Erycinidia* by the abbreviated cell of the hindwing, otherwise very near to it.

virgo. **P. virgo** *R. & J.* (99 b). Under surface dark olive-brown. Forewing white to the middle of the cell, with a broad white median band and four small, white-pupilled eye-spots, which are bordered on both sides by a grey line. ♀ beneath darker than the ♂, the white basal part reduced to a narrow stripe along the submedian. Hindwing of the ♂ with two bands, which form a Y, and a row of 5 ocelli, of which only the white

pupils stand out distinctly. ♀: hindwing beneath predominantly black with a yellow discal spot. Length of the forewing 25 mm. Only one pair yet known, discovered by Meek in the Aroa district.

9. Genus: **Platypthima** *R. & J.*

Likewise near to *Hypocysta* and hence also to *Argyronympha*, mainly with the same structure. Eyes hairy. Wings short and broad. The genus, the type of which is the figured *ornata*, embraces also a few species which for want of material cannot yet be definately proved to belong here. Only three certain species known as yet, all from British New Guinea.

P. ornata *R. & J.* (99 c). Under surface of the forewing unicolorous brown, but hindwing with varie- *ornata.*
gated markings, the arrangement of which somewhat recalls certain *Pedaliodes* from South America. Beyond the cell a spar-shaped yellowish stripe, distally bordered by a similar but red-brown one. Two larger round black, white-dotted ocelli with reddish bordering in the submarginal area. Hindwing in addition with a violet, metallic median band and a similar subterminal stripe. From 2000 m. Flies November to February.

P. simplex *R. & J.* Body and upper surface of the wings as in *ornata*, the white area of the forewing, *simplex.*
however, distally more rounded, the black admarginal line of the hindwing standing out somewhat more distinctly from the first median onwards. Under surface: forewing slightly tinged with purple, but with no trace of eye-spots, in place of which there is a fine undulate line, bordered by a small olive-coloured stripe. Hindwing densely scaled from the base to the apex of the cell, then a band-like olive-coloured median area, which is accompanied distally by a black and a metallic line. In addition about 5 ocelli and a metallic admarginal band. Length of the forewing about 18—20 mm. Only 2 ♂♂ known, from the Aroa region.

P. decolor *R. & J.* Body above dark brown, a broad lateral line on the palpi and behind the eyes *decolor.*
cream-coloured. Wings above brown, forewing in the basal half of the cell densely haired. Under surface: forewing with dark apex, a narrow, angled, cream-coloured band and three small ocelli. Hindwing dark olive-coloured, sprinkled with cream-white and chocolate-coloured scales, a yellowish white band, touching another narrower one, and four white ocelli. Length of the forewing 20 mm; only ♂♂ of this charming species as yet discovered. Locality likewise the upper region of the Aroa River, British New Guinea.

10. Genus: **Harsiësis** *gen. nov.*

The single certain species of this hitherto overlooked genus has been united with *Hypocysta*, from which, however, it is easy to separate by the broader cells on both wings and the longer upper discocellular of the forewing. Moreover in *Harsiësis* two subcostal veins arise far before the end of the cell, in *Hypocysta* only one, whilst the second arises directly at the end of the cell. The very long lower discocellular of the forewing more deeply incurved, not almost rectilinear. The ♂ bears in addition 3 tufts of hair at the anterior margin of the cell and on the submedian of the hindwing, which are absent in *Hypocysta*. Precostal straight, distally not excurved as in *Hypocysta*. Hitherto only known from the Papuan region and apparently like *Hypocysta* not even extending on to the eastern satellite islands of New Guinea.

H. hygea, of which there are three branch-races to record: **noctula** *subsp. nov.* (93 d), which is above *noctula.*
more uniform dark blue-grey than *hygea* from the Aru Islands. The subanal eye-spot on the underside of the hindwing is much smaller than in *hygea*. German New Guinea, very rare. Flies in January, mostly on the spurs of the mountains. — **hygea** *Hew.* Above differing from *noctula* in the paler grey, distinctly defined apical area *hygea.*
of the forewing. The silver-coloured median band on the underside of the hindwing scarcely half as broad as in *noctula*. Hitherto only recorded from the Aru Islands, apparently not extending to the Key Islands. Oberthür records an allied form from Andai near Dorey in Dutch New Guinea. — **jobina** *subsp. nov.* is the most *jobina.*
pronounced geographical subspecies. Upper surface transparent, light slate-grey, with brilliant blue metallic gloss in the cell. Under surface of the forewing with a broad whitish median area, the metallic band much restricted and narrowed by the large ocelli. Jobi.

H. hecaerge *Hew.*, described from New Guinea and certainly very rare, as since the time of Wallace *hecaerge.*
and Hewitson (thus the fifth and sixth decades of the last century) it has not again been brought to Europe and Hewitson's type is perhaps the only example known. ♀ differing from *hygea Hew.* in the more rounded wings and the presence of a large apical ocellus on the underside of the hindwing, so that the red-brown band encloses a double eye-spot. Forewing lighter grey than in *hygea*-♀, with a very broad pale yellow band, which is reproduced beneath. It is not impossible that *hecaerge* is only a pale aberration of *hygea*. Dutch New Guinea.

11. Genus: **Zipoetis** *Hew.*

An apparently nearly extinct genus, which has not yet been discovered outside the confines of the Indian Empire, but may probably still be expected from Tonkin.

Structurally *Zipoetis* (*Zipaetis auct.*) comes nearest *Coenonympha*, but only the costal vein is swollen, whilst there are other slight differences, e. g. the middle discocellular of the forewing is shorter than the straight lower discocellular. On the hindwing the precostal is worthy of note, its point being directed basad, not distad as in other genera. Only two species, both of which are rare.

scyllax. **Z. scyllax** *Hew.* (94 c), above black with somewhat lighter distal border, which is traversed by 2 anteterminal lines. On the underside of the hindwing the anterior ocellus is bi-pupilled. A rare butterfly, distributed from Sikkim to Tenasserim and inhabiting the hot valleys, apparently nowhere ascending above 1000 m. It flies from April to November and its habits are the same as in *Ypthima*.

saitis. **Z. saitis** *Hew.* never finds its way into continental collections, is unknown to me in nature and occurs in the mountains of South India from 300—1000 m. It is said to fly from April to September. Upper surface black with white obliquely placed subapical resp. submarginal bands, which are somewhat broader in the ♀, under surface with the eye-spots arranged nearly as in *scyllax*, but placed more in the middle of the cell, the anterior one being the largest. Larva on Ochlandra stridula (Thwaites).

Erebia Group.

This group, which is dominant in the Palearctic Region, sends off a few representatives only into southern China and the southern slopes of the Himalayas.

12. Genus: **Callerebia** *Btlr.*

Distinguished from *Erebia* by having the cell of the forewing broader, the middle discocellular only feebly angled and the lower discocellular almost straight and transversely placed. The precostal arises exactly at the point of origin of the subcostal and the structure of the hindwing further differs from *Erebia* in having the middle and lower discocellular of the same length, while the former in *Erebia* is much shorter. The habits and distribution have been already discussed vol. 1, p. 93.

narasingha. **C. narasingha** *Moore* is one of the rarest Indian butterflies, and although described as long ago as 1857 it has only once been found again, at Bernardmyo, Upper Burma, near the border of Yunnan, at an elevation of 5400 ft. above sea-level. Above the species may be compared with *Erebia cyclopius Ev.* (vol. 1, pl. 35 c), but it is smaller and beneath similar to *Ypthima megalomma Btlr.* (vol. 1, pl. 34 c) and even more to *Y. megalia Nicév.*, and thus it came about that it was originally taken by Moore for an *Ypthima* and placed in that genus. Forewing with a black, bi-pupilled, yellow-ringed apical ocellus, hindwing unicolorous grey, finely striated with black and otherwise without a trace of any marking or of ocelli.

mani. **C. mani** *Nicév.* (vol. 1, p. 110) above resembles *fasciata Hew.*, which is figured in the Palearctic part (vol. 1, pl. 35 e), and the red area of the forewing does not extend on to the hindwing. The species ascends in Ladak (Kashmir) to 13 000 ft.

kalinda. **C. kalinda** *Moore* above somewhat resembles *maracandica Ersch.* (vol. 1, pl. 35 e), but the reddish parts of the upper surface are yellowish and less broadly diffused. Underside of the forewing with the exception of the costal and submarginal areas red-brown, ocellus larger, bordered with lighter yellow than in *maracandica*, hindwing grey-brown, with very numerous delicate submarginal dots, placed at approximately equal distances. From 9—13 000 ft. in the western Himalayas, local, but not rare in places. Nicéville found it at the Nilang pass at an elevation of 16 000 ft.

shallada. **C. shallada** *Lang* (vol. 1, pl. 35 b) is somewhat larger than *kalinda Moore*, the reddish brown spots on the upperside of both wings smaller and deeper coloured and sharply separated from the eye-spot of the forewing. The iris of the ocellus less distinct. From the valley of the Upper Ganges, from about 2000—2500 m. on grassy slopes. Common in May at Dalhousie, and flying there even in the dense forests together with *kalinda*.

hyagriva. **C. hyagriva** *Moore* (vol. 1, p. 110), locally very common, at Mussourie, but only in August—September, on grassy mountain-slopes, also in Kashmir and the Kumaon Himalayas, but there local and rare.

nirmala. **C. nirmala** *Moore* (93 f) has been already discussed in the Palearctic part. Very common in the western Himalayas, where it is met with both in wet and rocky districts, and from 1000—2500 m. It is on the wing on *intermedia.* cloudy and even rainy days. — As **intermedia** *Moore* (vol. 1, pl. 35 b) has been described a form with distinct *cashapa.* median ocelli on the hindwing beneath and as **cashapa** *Moore* the Kashmir form has been separated, in which

4 ocelli are placed close together and give the impression of a rainy-season form. Larva on grasses, brown, with fine transverse stripes. Pupa similarly coloured, with a large dorsal protuberance and deep ventral incision before the abdominal segments.

C. daksha *Moore* (93 f) approaches *nirmala*, but is smaller, as has been already mentioned in the Palearctic volume, p. 94. Upper surface dark vinous red. Rare and local in Kashmir, flying at 7—9000 ft. from June to August. *daksha.*

C. scanda *Koll.* (vol. 1, p. 94, pl. 35 a). Under surface of the hindwing predominantly grey. Common everywhere in the western Himalayas from July to September, also known from Kashmir. Area of flight from 5—11 000 ft., flies most freely during the heaviest rains, resting on wet places in the damp woods or hiding in fern thickets. *scanda.*

C. annada is the largest, most variable and most widely distributed species of the genus. Larva and pupa do not differ essentially from those of *C. nirmala Moore.* — **annada** *Moore* (vol. 1, p. 93, pl. 35 a) may be regarded as the rainy-season form of the western Himalayas; **hybrida** *Btlr.* (vol. 1, pl. 35 a) is probably a smaller dry-season form of it. Both inhabit elevations of 4—7000 ft., where they are common everywhere from June to September on dry mountain slopes. — **orixa** *Moore* (vol. 1, pl. 34 f) is the well differentiated geographical form of the eastern Himalayas, where it occurs from the Khasia Hills to Manipur. In the large black apical ocellus of the forewing with red or yellow-brown bordering *orixa* already tends in the direction of **polyphemus** *Oberth.* (vol. 1, pl. 34 f), which is one of the commonest butterflies of western China. *annada. hybrida. orixa. polyphemus*

13. Genus: **Coenonympha** *Hbn.* (= Lyela *Swinh.*)

This genus, hitherto alien to the Indian fauna, seems to be slowly spreading eastwards, for it is already reported by Swinhoe from Beluchistan. Only one species is known from there, on which Swinhoe erected a separate genus which he compares with *Erebia*, although he states that the structure is identical with *Coenonympha*. On the genus cf. further vol. 1, p. 143—147, pl. 48, and vol. V, pl. 50.

C. myops, distributed from the Achalzik region and Alai, splits up into three local races: **myops** *Stgr.* (vol. 1, p. 143). Forewing with large apical eye-spot, hindwing with dark median band. From Ala-Tau and Alai. — **tekkensis** *Stgr.* (vol. 1, pl. 48 b) has the apical eye-spot still larger and the median band of the hindwing darkened. — **macmahoni** *Swinh.* approximates to both races. Upper surface brown, nearly black, in some ♂♂ and beneath even darker than above. Forewing with a large round, blackish spot with broad dark orange-coloured border. Sometimes this ocellus bears a white pupil. The ♀ has somewhat longer wings, which consequently appear narrower, and is slightly paler than the ♂. From Quetta in Beluchistan. *myops. tekkensis. macmahoni.*

14. Genus: **Argyrophenga** *Dbl.*

Nearly allied to *Erebia*, but differs in the short antennae, the long palpi and the long body, and structurally in all the subcostal veins arising distally to the apex of the cell. Only one species known, which altogether resembles the subalpine *Erebia* in its habits and flight and inhabits New Zealand, where it was discovered by P. Earl on a plain in the south.

A. antipodum *Dbl.* (93 g) above resembles an *Erebia stygne O.*, except that it has more extended and lighter red areas round the ocelli, which contain larger white pupils, those of the forewing showing two, those of the hindwing only one each. Both wings are bordered by a brown, sharply defined marginal band. New Zealand. *antipodum.*

Satyrus Group.

The numerous species of this group form a considerable proportion of the Palearctic forms, especially in the Mediterranean regions. But in the Asiatic tropics they are less numerous and there are only a few genera to record here, most of which line the boundary of the Palearctic zone.

15. Genus: **Erites** *Westw.* *)

Through the genitalia resp. clasping-organs this rather isolated genus is to a certain extent connected with the European *Perarge*. The valve is narrow, anteriorly obtusely sloping, the uncus long, with very fine, pointed, delicate lateral clasps. On the forewing only the costal is inflated, the cell long and narrow, occupying almost ⅔ of the length of the wing, closed by a short upper discocellular, a moderately angled middle and a straight and but little longer lower one. The hindwing is strongly dentate distally and has the precostal directed basad. Secondary sexual characters are wanting, the markings which in the ♂♂ are yellow beneath only, in the ♀♀ are yellow also above. Legs of the ♂♂ short, hairy, those of the ♀♀ longer, more slender, without hairs. Some transparency of both wings is common to all the species.

*) The genus *Ragadia* morphologically approximates more nearly to *Erites* in the shape of the clasping-organs than to the Mycalesids, with which, following other authors, we have included it.

The butterflies inhabit the Macromalayan region with one branch to Tenasserim and Tonkin, but do not extend eastwards beyond Bali. Early stages unknown. The *Erites* seem to prefer the plains to the mountains, on Java I did not meet with them above 600 m. and the Tonkin form occurs at about the same elevations.

The flight is weak and low, with frequent intervals of rest, when the insects settle with folded wings on lower leaves or after the manner of certain *Mycalesis* even on the ground, disappearing among the dry leaves.

E. medura is the largest and most richly coloured species and at the same time the most widely distributed on the continent, as a branch race has been described from Cachar, also found by me in Tonkin. *medura* further inhabits Burma and Java, and hence will surely yet be discovered in Perak or elsewhere on the Malay Peninsula, and affords fresh evidence of the former land-connection between Further India and Java, and even with the addition of Sumatra and Borneo, which must already have been separated when *medura* emigrated from Java to Cachar or more probably vice versa. — **medura** *Horsf.*, the first discovered species of the genus, is one of the commonest butterflies along the south coast of Java, where it begins to appear in abundance at the end of the rainy season, February—March, preferring the open woods, and can easily be taken on sunny days at the edges of the paths. In East Java *medura* is commoner than in the west of the island and Doherty told me that he had met with it on the southern slopes of the volcano of Semeru, East Java, in astonishing numbers. But *medura* does not ascend above 600 m. into the mountains. The species may be recognized at a glance by the presence of the row of ocelli on the hindwing above; this consists of five ocelli, arranged as follows: first a minute, scarcely perceptible costal eye-spot and then four contiguous ocelli of equal size, with thick black pupils and broad yellow bordering, which in this form and colouring occur only in *medura* and its subspecies. The equal size and the contiguity of the ocelli is the characteristic for *medura*. In addition the anal ocellus of the forewing in both sexes is large and prominent and shows through so strongly on the upperside that it really belongs also to this surface; it shows, however, at most in the ♀ and in East Javan specimens the trace of a white pupil; above it on the under surface there are always only three small ocelli, also distinctly visible above, and very constant, showing no variation even when a large series is examined; all the other species possess four small ocelli. The large ocellus of the forewing has on the under surface a bright silvery pupil, placed exactly in the centre. The discal, proximal band is straight, but is constricted at the point where it is intersected by the median vein; the median, distal band, which in ♂ and ♀ shows through distinctly yellow on the upperside also, has near the anal margin, exactly midway between lower median vein and submedian, a small bend distad, which is entirely absent in *angularis*. The marginal lines are very well developed. The ♀ differs from the ♂ in the lighter ground-colour, larger expanse, broader wings and larger ocelli. East Javan specimens — I possess some from Malang — are considerably lighter and the median, distal band of the hindwing beneath has in the middle, about over the third median vein, only a very indistinct black border and even shows a tendency to become confluent with the yellow foreground of the adjacent ocelli three and four. *medura* has been taken by Doherty (Nicéville, Journ. As. Soc. Beng. vol. 66, 1897, p. 679) also on Bali, the most easterly record for the genus; my collector, who worked the island for two months, failed to find it; it probably shows the peculiarities of the East Javan form intensified (Martin). — **falcipennis** *W.-Mas. & Nicév.* (93 e) is really only an enlarged *medura* with still larger ocellus on the forewing, above which, just as in *medura*, are placed three smaller eye-spots together. The ♀ bears still more completely circular and more broadly yellow-margined eye-spots on both wings and the yellow angular band on the upperside of the hindwing is as distinct as in *medura* ♀. *falcipennis* was described from Cachar from an example of the dry season (93 e 1), whilst **roduntata** *Nicév.* is the rainy-season form, of which we (93 e 2) figure a ♀, which is in my collection from Tenasserim. Of the form *falcipennis* I myself took examples identical with Moore's figure (Lepidoptera Indica II, pl. 121, fig. 3 and 3 a) in Central Tonkin at Chiem-Hoa, August—September. Both *medura* races have in common four contiguous eye-spots of equal size, strongly margined with yellow, on the upper surface of the hindwing, by which they are easy to separate from the offshoots of a species likewise occurring on the continent, but smaller, namely

medura.

falcipennis.

roduntata.

E. argentina, which shows on the upperside of the hindwing 5 widely separated eye-spots, decreasing in size from the anal angle to the costal area. In all the forms there are further 4 small eye-spots on the underside of the forewing, which are of nearly equal size, where in *angularis* and *medura* we only find 3 subapical ocelli. — **argentina** *Btlr.* (93 e as *ines*) is the race from northern Borneo, the type having come from the island of Labuan, the coaling-station of the sultanate of Brunei. It is strikingly light and much more resembles the Javan *fruhstorferi* (93 e) than **ines** *Fruhst.* (93 e as *argentina*), from the south and south-east of Borneo. *ines* again much more approximates to the Perak subspecies and the form from Sumatra than to its own sister-race from North Borneo. — **delia** *Mart.*, from Perak and Sumatra, also known from Banka, is beneath darker grey and bears somewhat narrower brown longitudinal bands than *ines*; it differs from specimens from Labuan

argentina.

ines.

delia.

and Borneo chiefly in that the median band on the hindwing beneath is well margined with black distally and is never placed so near to the fourth and smallest ocellus, but on the contrary there is always a remnant of ground-colour between band and ocellus; the anal ends of the two bands on the hindwing beneath do not converge so strongly at the margin of the wing as is the case in typical specimens. Described by Martin from 11 ♂♂ and 2 ♀♀ from Deli on the north-east coast of Sumatra, also in coll. Fruhstorfer in large numbers from the neighbourhood of Padang. — **fruhstorferi** *Mart.* (93 e) may be distinguished at once from *medura*, which flies in the same districts, by the ocelli of the hindwing being separated and decreasing in size and by showing distinctly 4 small ocelli above the large anal ocellus of the forewing. Yellower, lighter and smaller than typical *argentina* and *delia*, the underside of both wings is without the slight violet gloss („purplish" of English authors) which shows very distinctly in the forms already mentioned; the bands are yellow and not brown, but the median, distal, angled one possesses a character peculiar to the Javan subspecies, a yellow spur running proximally along the margin of the cell, which where the band leaves the cell accompanies the latter for a short distance, but does not reach the discal straight band. That Java with its rich fauna should produce more than one species of *Erites* was *a priori* to be expected. Described from a ♂ from South and a ♀ from West Java; in the Fruhstorfer collection at Geneva there are further examples; the insects must, however, be rather rare, for in numerous consignments of butterflies from Sukabumi, which I have carefully looked through, there were many *medura*, but not a single *fruhstorferi* (Martin). *fruhstorferi.*

E. angularis is chiefly characterized by having the proximal band of the hindwing angularly broken. Apex of the forewing somewhat falcate, in the anal angle of the forewing a large ocellus, and above it along the margin of the wing 4 smaller eye-spots, which, however, are wanting in the dry-season form, but may otherwise be occasionally absent. — Two branch races: **angularis** *Moore*, type from Upper Tenasserim at elevations of 3—5000 ft., also known from Pegu, is represented in my collection by a large series of examples from Perak. The dry-season form was found by me at the borders of Siam and Burma, near Kanburi, West Siam, in April. — **pseudofalcipennis** *form. nov.* In this the anal ocellus of the forewing shows through but weakly above, and the under surface resembles the figured *falcipennis* (93 e), except that the eye-spot of the forewing with its yellow bordering is pointed-oblong and the ocelli of the hindwing are a little longer. — **sumatrana** *Mart.* A local form of somewhat darker colouring, on the under surface of the forewing, in particular, it closely approaches typical *angularis* from the Malay Peninsula, but it is on the whole a decidedly darker insect; the median, distal band of the hindwing in the ♀ shows through but little yellow above and then only for a short distance along the apex of the cell, whilst in typical ♀♀ this band shows yellow on the upperside for its whole length; of the 5 ocelli of the hindwing above the second and fifth are distinctly the largest in both sexes, whilst in *angularis* from the mainland the fourth and fifth show the largest diameter; the 4 small ocelli placed over the large anal ocellus of the forewing are mostly complete, the upper, costal one is never absent, the fourth and lowest but rarely; in the ♂ the black marginal lines on the underside of the forewing show quite distinctly, whilst in continental specimens they are hardly discernible. In North-East Sumatra this species was by far the commonest of the three *Erites* occuring there. *angularis.* *pseudofalcipennis.* *sumatrana.*

E. elegans is a pretty species, and deserves its name; from all the other *Erites* it is distinguished at a glance by the absence of the large anal ocellus of the forewing, on the underside of which are placed 5 about equally large, or rather equally small ocelli. Moreover the bands of the forewing, which are very distinctly visible on the upper surface, present a characteristic feature in that they run completely parallel and are distinctly convex towards the base of the wing; in all other *Erites* the proximal band is fairly straight and only the distal one, turning aside from the large anal ocellus, shows a convexity directed towards the base. The discal, proximal band of the hindwing is straight, as in all the species with the exception of *angularis*, but the median, distal band is twice bent, the first time about over the middle of the second subcostal vein, the second time over the base of the upper median vein; only *angularis* shows exactly the same conformation of this band. In consequence of the bend above the second subcostal vein the end of the band converges strongly at the costal margin of the hindwing with the end of the discal, inner stripe and in set specimens is more inclined to meet the proximal band of the forewing than the distal one which really corresponds with it, a condition which is not found in *angularis*. The ♀ of *elegans* is larger than the ♂ and has broader wings, the bands of the forewing very distinct on the upper surface also; on the upperside of the hindwing the distal band is distinctly yellow and the ocelli have broader, brilliant yellow margins; the upper, costal ocellus of the row on the hindwing is no longer visible on the upper surface, while in the ♂ it has not entirely disappeared. A further peculiarity of the 3 middle ocelli of the hindwing in the ♀ consists in their having the black pupils not placed exactly in the centre, but removed eccentrically towards the margin of the wing, so that the eye-spots present a comical, squinting appearance (Martin). — Two geographical races may be separated: **elegans** *Btlr.* (93 e), just described, from North Borneo, which is represented in coll. Fruhstorfer by 2 examples from South-East Borneo and according to Shelford also occurs in Sarawak, where it has perhaps developed a local race, **thetis** *Shelf.* — But *elegans.* *thetis.*

distincta. **distincta** *Mart.*, from Sumatra, is certainly different from *elegans*, but may be recognized at once by the two bands on the hindwing beneath touching one another above the discoidal vein, whilst in Borneo specimens they are widely separated; the proximal angle corresponding to the two distal angles nearly touches the distal margin of the proximal band. *distincta* is moreover larger and perhaps a shade darker than typical *elegans*. From two ♂♂ and six ♀♀ from Deli, North-East Sumatra. It is certainly striking that in the comparatively small district of Deli three different species of *Erites* fly together and one might hence assume that just here there is a particularly favourable combination of all the conditions of climate and flora necessary to *Erites*; on the other hand it is not impossible that in other places also in the Indo-Malayan region *Erites* is equally well represented, but that the inconspicuous insects, having nothing to catch the eye of the dealer, have escaped observation and capture. It is still quite likely that a form of *elegans* may be added from the Malay Peninsula (Martin).

16. Genus: **Xenica** *Westw.* (= Argynnina, Geitoneura *Btlr.*).

With this genus begins a trio which only occur in Australia and Tasmania and show in common the peculiar yellow-brown colouring which somewhat recalls our *Pararge megera* (vol. 1, pl. 45 d), but must there be regarded as the result of adaptation to its surroundings. On the forewing two principal veins (the median and the submedian) are cystose, whilst the costal remains unaltered, by which *Xenica* is easily distinguished from the following genus *Heteronympha*, which has the three principal veins inflated. Upper discocellular very small, middle one proximally curved and as long as the lower. Precostal of the hindwing short, knobbed. The cell obliquely closed. There are about 9 species known.

achanta. **X. achanta** *Don.* (93 c) is the commonest species of the genus and distributed from South Australia and New-South Wales to southern Queensland. Under surface of the forewing as above, but the grey underside of the hindwing beautifully marbled with delicate brown patches of the most various shapes, among which are placed the two ocelli, of almost equal size but widely separated. Before the distal margin in addition two thin brown longitudinal bands. ♀ relatively rare, larger and lighter yellow than the ♂.

klugi. **X. klugi** *Guér.* (93 c), a smaller and much rarer species, bears above stronger black longitudinal and transverse bands and on the hindwing smaller eye-spots. Beneath in the dry-season form the apex of the forewing and the hindwing are grey with darker distal margin, inclining to brown, and an almost black, quadrate median spot. In the rainy-season form the median spot is lengthened into a band, traversing the entire wing, and the ocelli of the upper surface are distinctly reproduced. From southern Australia and Tasmania.

hobartia. **X. hobartia** *Westw.* (93 c) is always found together with *klugi* and the range of the two also coincides geographically. The under surface differs from that of the dry-season form of *klugi* in the more distinct black cell-spot of the forewing and the more distally placed transverse spot of the hindwing, which is of red-brown colour and finely marbled with grey.

tasmanica. **X. tasmanica** *Lyell* is a species which is only known to me through Waterhouse, Catalogue Rhop. Austr., 1903, and occurs only on Tasmania.

kershawi. **X. kershawi** *Misk.* (93 c) bears on the underside of the hindwing between finely divided longitudinal bands similar stripes covered with silvery scales. The ocelli are extremely delicate, the apical eye-spot of the
ella. forewing nearly suppressed. Very local, only known from Victoria and New South Wales. As **ella** *Olliff* has been described a dry-season form of this interesting species, which Waterhouse registers as a variety.

lathoniella. **X. lathoniella** *Westw.* (93 c) has more rounded wings than *kershawi*, above predominantly yellow-brown, as the black longitudinal bands are shorter than in *kershawi*. The markings of the hindwing more extended in width than in length. Silvery bands of the under surface fewer but more extended. The name *lathoniella* is
orichroa. very aptly chosen on account of the similarity of this *Xenica* to the European *Argynnis lathonia L.* — **orichroa**
paludosa. *Meyr.* is a mountain form of *lathoniella* and **paludosa** *Luc.* an insular race from Tasmania. Distribution of *lathoniella* only in Victoria and New South Wales.

correae. **X. correae** *Olliff* is the ♀ (and **fulva** *Oll.* the ♂) of a rare species, which was first discovered in 1889 and
fulva. is reported from Victoria and New South Wales. Unknown to me in nature. Has fine median band on the under surface and small anal ocelli.

lepera. **X. lepera** *Hew.*, exclusively from Tasmania, is likewise only known to me from the figure and about agrees in size with *kershawi* and *lathoniella*. Upper surface darker brown with yellowish basal half, which is slightly scaled with brown. Forewing with a small black transverse spot at the discocellular. Hindwing with an angled yellow median band. Under surface: forewing with broad

black apical patch, which is divided into two halves by a yellow stripe. Hindwing brown, in the middle with a yellowish band sharply directed basad, below which are placed two very small black eye-spots.

17. Genus: **Heteronympha** *Wallengr.* (= Hipparchioides *Btlr.*).

The few species of this sharply defined and handsome genus resemble *Xenica* in colouring, and hence again our *Pararge megera*, and are distinguished by their sexual dimorphism. In contrast to *Xenica* all the three principal veins of the forewing are thickened. *Heteronympha* differs from *Xenica* and the other allied genera of the *Satyrus* group chiefly in the regularity of the closing veins of the short cell of the hindwing. All the known species inhabit Australia and Tasmania.

H. merope *F.* (= oenomais *Hbn.*, archemor *Godt.*) (94 b) is an extremely common species, occurring in many thousands; its sexual heteromorphism is illustrated by the figures. But like *Xenica*, *merope* is also an extremely constant species, which may indicate its great geological antiquity and the consequent fixity of its development. Except that the transverse band of the ♀♀ is at times somewhat more or somewhat less strongly developed and the red-brown colour very slightly lighter or darker, long series show no deviation from the normal. Under surface of the ♂♂ uniform grey-brown with some fine red-brown undulate lines on the hindwing; underside of the hindwing in the ♀♀ sand-coloured, grey, with a darker shade across the middle. From South Australia to Southern Queensland. — **suffusa** *Skuse*, from Victoria and New South Wales, appears to belong to a dry-season form; it is only reported from Victoria. — **duboulayi** *Btlr.* is a West Australian local race, only known to me from Butler's description, who separates it on account of the somewhat differently shaped wings and the altered position of the bands and lines, the smaller ocelli of the forewing and the larger of the hindwing. Under surface of the hindwing with only one small eye-spot. — **salazar** *subsp. nov.* is a small and dark island race which Butler recorded from Tasmania as long ago as 1866. — Larva brownish, on tufts of grass, hiding by day at the roots; pupa in a loose cocoon on the earth. *merope.* *suffusa.* *duboulayi.* *salazar.*

H. philerope *Bdv.*, occurring from West Australia to Victoria and New South Wales, also known from Tasmania, is very nearly allied to *merope*, the ♂ only differing in the more longitudinal instead of horizontal black bands on the forewing, which are at the same time purer black and more sharply defined. The ♀ bears three subapical patches instead of one and a broad, black, continuous border to the hindwing, only in the median part deeply excised, with fine black undulate lines beyond the cell and a narrow distal border, which sends out a black tooth towards the middle of the second median. Under surface, as in *merope*, with blackish shading in the middle of the wings. *philerope.*

H. mirifica *Btlr.* (= digglesi *Misk.*), occurring from Sydney to Brisbane, but very rare in European collections, is a conspicuous species with black upper surface. Forewing traversed by a twice angled yellow-brown band and with a not very large, nearly quadrate subapical spot. Hindwing with a small, white-dotted subanal ocellus. Under surface as above, but with the apical part of the forewing finely marbled. Hindwing beneath as in *merope*, but with two very small subanal ocelli. *mirifica.*

H. banksi *Leech* (= gelanor *Godt.*, affinis *Luc.*) is only known to me from Godart, who again knew only the ♀. Waterhouse gives New South Wales, Victoria and Brisbane as localities. Upper surface brown-black with yellowish patches. The forewing bears six, namely two subapical and four obliquely placed in the disc. The hindwing bears five, a very large subanal ocellus, above which are placed four smaller ones nearer to the distal margin. Under surface of the forewing with a small apical ocellus on an ash-grey ground-colour. Hindwing glossy grey-violet with two small subanal ocelli. *banksi.*

H. paradelpha *Lower*, from the southern provinces of Australia, is described in an Australian periodical to which I have not access and is unknown to me in nature. *paradelpha.*

H. cordace *Hbn.*, described and figured about 1832 in the „Zuträge", is not known to me. Waterhouse records it from Victoria and New South Wales. On the upper surface it resembles *Xenica achanta*, but the black markings are thicker, almost as in *Xen. hobarta*. From the latter, however, it is easy to distinguish by the under surface of the hindwing (not bark-grey, but spotted with ochre-yellow, and with the ocelli as in *achanta*). *cordace.*

18. Genus: **Enodia** *Btlr.*

This genus should by rights be called „*Tisiphone Hbn.*", as there can be no doubt at all that the real type came from Australia. But since in vol. V, p. 184, the name has already been incorrectly employed for a South American genus (*Manataria Kirby*), it cannot be used again here and we confine ourselves to pointing out the correction, which must be taken into account in future revisions. — In size approaching *Heteronympha*, the few species of *Enodia* (all of which are rare) chiefly differ in the darker, almost predominantly

black ground-colouring and in the middle discocellular of the hindwing being even more sharply angled than in *Xenica*. — None of the species yet described is found outside the continent of Australia.

abeona. **E. abeona** *Don.* (= zelinde *Hbn.*) (94 b). An extremely variable species, no two specimens alike; in this respect the forms of *Enodia* differ considerably from those of *Heteronympha*. The under surface of the wings is even more handsome than the upper, the hindwing being traversed by a broad, pure white band, distally finely dentate, and the ocelli with their distinct, dark red iris stand out even more strongly. I have ♂♂ before *rawnsleyi.* me from Sydney in which the band is reduced to a fine white line, and **rawnsleyi** *Misk.* is a colour aberra- *joanna.* tion in which it is entirely absent. — **joanna** *Btlr.*, one of the most beautiful butterflies of Australia and of the whole East, cannot be specifically separated from *abeona*, in spite of all the differences in colouring, on account of the early stages. Both wings are traversed by yellow longitudinal bands on a black-green ground. Forewing with large blue ocelli, which on the hindwing become very small, but are broadly bordered with red. — Larva green with rounded head and 2 anal points; on grass. — Pupa emerald-green, the margins of the wing-cases yellow. — From the Clarence River.

helena. **E. helena** *Oll.* (94 b) according to Waterhouse only inhabits the mountains. This very rare species is easy to separate from the commoner *abeona* by the broad yellow band of the forewing, which is quite differently placed. From the Cairns district, Australia.

19. Genus: **Lamprolenis** *Godm. & Salv.*

Lamprolenis differs in habitus from *Mycalesis* in the elongate hindwing, recalling *Amathusia*, but has in common with *Mycalesis* the three inflated veins and the sexual mark on the hindwing. — The neuration of the hindwing approaches *Mandarinia*, the structure of the forewing forms a transition to the *Satyrus*-type, much as the shape of the hindwing leads over from *Ptychandra* to the *Lethe*-type. A character found exclusively in *Lamprolenis* is that the veins of the forewing are quite as swollen on the under surface and of transparent amber-colour. The swollen part of the submedian is strongly bent, so that between it and the fine submarginal there is a deep cavity, which is covered with dense black scales. Below the submarginal the inner margin is twice folded and bears dull glossy scent-scales. Only one species yet discovered, which is confined to New Guinea.

nitida. **L. nitida** *Godm. & Salv.* (94 c). The figure shows the characteristic of the species, a wonderful green reflection, which gradually changes distad into a more intensive and brilliant golden bronze-colour, a decoration with which no other Indo-Australian Satyrid can even distantly compare. The very rare ♀ is essentially larger, paler brown, the hindwing shows only slight traces of the metallic sheen, but is instead ornamented with a very large black ocellus with brown-yellow border, which is always well developed on the forewing also. In the ♂♂, as also on the example figured, the anal ocellus on the upperside of the hindwing is commonly absent. According to Hagen the species flies in the woods at Astrolabe Bay, in March. I myself have received it from the neighbourhood of Friedrich-Wilhelmshafen.

21. Genus: **Maniola** *Schrank.*

The few South Asiatic species of this purely Palearctic genus and its generic diagnosis have been already fully dealt with in vol. I, p. 137-—142, so that we give here simply an enumeration of the Indian species. The name *Epinephele Hbn.* is about 15 years younger than that of *Maniola*, to which it must sink. *Maniola* has also already been employed by Bingham in the Fauna of British India for the forms in question.

davendra. **M. davendra** *Moore* (= roxane *Fldr.*) (vol. I, p. 142, pl. 47 g) inhabits the north-western Himalayas, where it flies at elevations of 9—12 000 ft. on hot days in June or July over stony slopes, which are only *latistigma.* partly overgrown with brown grass and especially with Artemisia and Ephedra. — The form **latistigma** *Moore* *brevistigma.* was met with by Colonel Swinhoe near Quetta at about 2000 m. from June to August, and **brevistigma** *Moore* *tenuistigma.* appears to be the high alpine form, as it was found at Kardong as high as 14000 ft. in August. — **tenuistigma** *Moore* was taken in Beluchistan, flying in June.

M. narica Hbn. (vol. I, p. 139, pl. 46 d) is distributed through the steppes from Turkestan to Afghanistan.

cheena. **M. cheena** *Moore* (vol. I, p. 140, pl. 47 a, b) flies over grass and pasture-lands from June to August *kashmirica.* in the western Himalayas near Kunawur at elevations of 8—10 000 ft. — **kashmirica** *Moore* is a local race, which has been taken from June to September in Kashmir.

interposita. **M. interposita** *Ersch.* is the Indian offshoot of the widely distributed *lycaon*, which flies in Afghanistan from May onwards.

M. pulchella *Fldr.* (vol. I, p. 140, pl. 48 a) flies in the western Himalayas and Kashmir from June to September and ascends to 15 000 ft. — **neoza** *Lang* (vol. I, pl. 48 a) is very common in certain parts of Kashmir, such as at Goolmurg, and is said to occur from June to August from altitudes of 10—12 000 ft. — **pulchra** *Fldr.* (vol. I, p. 140), a geographical form which was recorded at the Shandur Plateau in North Kashmir and from Kunawur from June to September at 8—10 000 ft. The missionary Francke sent me the two last named forms from Kulu, where they occur together. *pulchella.* *neoza.* *pulchra.*

M. coenonympha Fldr. (vol. I, p. 140, pl. 47 a) is very rare and local, only known from Ladak. — *maiza Lang* is an aberration which was met with once at Goolmurg in Kashmir in great numbers in July from 9—10 000 ft. — *goolmurga Lang* comes from Kashmir from 11—13 000 ft. and was found sparingly in July and August.

21. Genus: **Karanasa** *Moore.*

If it is considered justifiable to divide up the species which are included in catalogues under the genus *Satyrus*, the name „*Karanasa*" must be introduced for those species which are grouped round the European „*actaea*" and „*cordula*" and were apparently left by earlier authors without generic names or united under those names which either apply to other groups of species or are synonymous therewith. That certain groupings based on the structure of the forewing are possible has also been recognized by Schatz, and the antennae of the several species likewise admit of a grouping, but this can be arrived at with still greater certainty on the form of the discocellulars of the forewing or a consideration of the cystosis of the principal veins. In this case the separation is conceivable

a) of *Minois Hbn.* with *dryas Scop.* as type,
b) of *Oreas Hbn.* with *circe* as type, but *Oreas* being preoccupied (Desmarest 1804, Mammalia) this name may be replaced by *Brintesia nom. nov.*,
c) of *Eumenis Hbn.* for *fagi Scop.*, *alcyone*, etc.

Hübner's type of *Eumenis* is *semele*, which differs indeed from the forms of the *fagi* series in the shorter antenna, but its structure affords no support to its separation under the name *Nytha*, as has been done by Bingham in the „Fauna of British India".

In *Karanasa* only the costal of the forewing is materially thickened, as is also the case in *Oreas Hbn.* = *Brintesia*, from which, however, it differs in the more strongly angled middle discocellular of the forewing and the shorter precostal of the hindwing.

K. huebneri *Fldr.* (vol. I, p. 127) is broken up into several races mentioned in the Palearctic part, thus **cadesia** *Moore* (vol. I, 43 d) is known from Kashmir, where it is very local, is but rarely found in large numbers and ascends to 13—17 000 ft. — **leechi** *Moore* is recorded from Baltistan and Ladak in the same high-alpine region. — **modesta** *Moore* (vol. I, p. 127), from Lahul and Kashmir. Flies July to August. *huebneri.* *cadesia.* *leechi.* *modesta.*

K. pimpla *Fldr.* (= monoculus *Fruhst.*) (vol. I, p. 131) is a geographical branch of our *actaea*; described from Kashmir, but also occurring in Beluchistan and Afghanistan. Flies in July to September at altitudes of about 2500 m. *pimpla.*

K. digna *Marsh.* (vol. I, p. 130), very similar to the South European *actaea*, is extremely rare and only known from the Shandur plateau and Gilgit in Kashmir. *digna.*

22. Genus: **Eumenis** *Hbn.*

The few South Himalayan species of this genus reveal the closest relationship with their trans-Himalayan sister-species and are consequently also fully dealt with in the Palearctic part (p. 127 ff.; pl. 43). The genus is distinguished by the cystose costal and median veins, and hence is distinguishable at first glance from *Karanasa* and *Oreas*. Palpus strong, with small terminal joint; antenna with shovel-shaped club; lower discocellular straight. Eyes not hairy, in which *Eumenis* differs from the otherwise nearly allied *Satyrus* (*Parage*).

E. thelephassa *Hbn.* (vol. I, p. 127, pl. 43 e) is one of the commonest and most conspicuous butterflies of anterior Asia and in Beluchistan and Afghanistan passes over into the Indian Region, occurring on rocky slopes from the middle of May from 6500—8000 ft. During the hottest part of the day the butterfly hides in the shade of rocks and stones, coming out again and flying about in the evening, when it is easy to catch *thelephassa.*

E. mniszechi *Fldr.* extends into the region of Kashmir and Kunawur in two interesting and apparently rare races, the names of which have been incorrectly transferred by dealers to Central Asiatic butterflies. — **lehana** *Moore* is discussed in vol. I, but the figure vol. I, pl. 43 f. does not agree with the examples received by me through the missionary Francke direct from Leh nor with Moore's figures of his undoubtedly true *mniszechi.* *lehana.*

Kashmir butterflies. *lehana* was discovered by Dr. Stoliczka and flies at Leh from June to September at elevations of 12—15 000 ft. The ♀♀ are larger than the figure in vol. I, and the anal ocellus of the fore-
baldiva. wing always smaller. — **baldiva** *Moore* is a darker race, with somewhat narrower ochre-coloured band on the upperside of the wings and white-pupilled ocelli on the forewing. It was discovered by Col. Lang, on the bare, brown, stony mountain-slopes of Spiti in Tibet, where it flies on hot days in June and July at
esquilinus. elevations of 7—10 000 ft. — As **esquilinus** *subsp. nov.* is described the geographical form from Alai, circulating as *lehana*, which differs from *lehana* from Kashmir in its small size, the ochre-coloured longitudinal band of the forewing, which, particularly in the ♀, is proximally strongly incised and more sharply defined, and the much darker uniform brown under surface not lightened with whitish yellow inclines more to the Turkestan Race, whilst examples from Tianshan nearly approach the true *lehana* beneath. *clarissima Seitz* is near *lehana Moore*, except that in *lehana* the bands are still broader. West China.

persephone. **E. persephone** *Hbn.* (= anthe *O.*). This beautiful, variable and abundant Anterior Asiatic race has likewise found its way across Persia to Afghanistan, where Col. Swinhoe met with it at Kandahar in May.

heydenreichi. **E. heydenreichi.** This magnificent Central Asiatic species occurs at Kashmir in the Indian Region,
shandura. where **shandura** *Marsh.*, figured vol. I, pl. 42 d, was discovered on the Shandur plateau at about 13 000 ft.
hegesander. An unusually dark race. — **hegesander** *subsp. nov.* has recently been observed in Tianshan. In this the white median bands of both wings are almost twice as broad as in *heydenreichi* from Alai and the figure in vol. I on pl. 42 d, and the under surface is marbled with yellow instead of black-brown.

parisatis. **E. parisatis** *Koll.* is in size similar to our *fagi Scop.*, but by reason of its characteristic colouring (the sharp contrast of the white distal border of both wings to the ground-colour), which varies from black-brown in the ♂♂ to slate-grey in the ♀♀, one of the most striking of the Satyrids. Like our *fagi* the species is nowhere rare. The Indian Region produces two local races, which were first correctly separated by Seitz, for neither Nicéville nor Bingham and Moore mention the fundamental difference between *parisatis Koll.*, with narrow white band on the upper surface and thread-like longitudinal band on the under (vol. I, pl. 44 e),
macroph- and **macrophthalmus** *Evers.*, with gigantic ocelli, which are also still more broadly margined with light yel-
thalmus. low, and more prominant white median band. All the above named writers on the Indian butterflies figure *macrophthalmus*. I have before me large series of *parisatis* from the Indian North-West Provinces and of *macrophthalmus* from Kashmir from 10—14 000 ft.

diffusa. **E.** *semele* **diffusa** *Btlr.* This offshoot of our common *semele L.* is a great rarity and was once taken in the North-West Provinces; it differs from its European sister-race in the reduction of all the red-brown patches and the darkening of the under surface.

The description of a few Palearctic forms, which stand in the closest relationship to the preceding Indian species, is here added:

minutianus. **E.** *regeli* **minutianus** *subsp. nov.* Allied to *corlana Stgr.*, but easy to distinguish from it by the broader black median bands of the wings and in particular by having the ocelli of the forewing almost half as large again. Moreover the anal eye-spot of the hindwing above is larger than in examples from Naryn and Tianshan. Common in Alai.

orchomenus. **E.** *autonoë* **orchomenus** *subsp. nov.* differs from examples from Turkestan and those from Naryn in its larger size and its lighter wings (as in *alcyone*), which show a yellowish submarginal area round the ocelli in the ♂ also. Under surface washed-out pale grey. ♀ very large as in *cordula miluda* from Zermatt, with a light yellow antemarginal area on both wings. From Tianshan.

aristonicus. **E.** *geyeri* **aristonicus** *subsp. nov.* is much smaller than the form from Anatolia and Armenia. Upper surface lighter grey; under surface of the hindwing with more indistinct markings and more indistinct undulate lines. From Amasia.

23. Genus: **Aulocera** *Btlr.*

A sharply defined genus even in the uniform shape and colouring of its few species, while in its structure it is the best characterized of all the series of forms grouped round *Eumenis* and *Minois*. In the first place the cell of the forewing is strikingly long, recalling that of *Brintesia*, and the markings also agree most with *circe*, the only species of the latter genus. *Aulocera* has the cystose costal in common with *Minois*, *Brintesia* and *Karanasa*, but differs from all the genera or subgenera hitherto united under *Satyrus* in the distally angled lower discocellular of the forewing and still more in the extremely narrow cell of the hindwing, which is scarcely half as long. The precostal of the hindwing arises as in *Karanasa* at the bend of the subcostal. Eyes not hairy.

The species of the genus are predominantly Palearctic and where they pass over into the subtropical and tropical region they only inhabit high alpine districts.

The genital clasping-organs differ very considerably from those of *Eumenis* in the absence of the thin, pointed, lateral clasps, in place of which there is a thick, obtuse, almost straight and sharp-edged ridge. Moreover the valve is more deeply excised than in European *Eumenis*, densely long-haired, basally with a strong protuberance.

A. brahminus *Blanch.* (vol. I, p. 122, pl. 41 c) is the smallest Indian species, and is easy to recog- *brahminus.*
nize by the narrow white longitudinal band of both wings, which is sometimes completely obliterated towards the anal angle of the hindwing. This form is **scylla** *Btlr.*, which was discovered near Nepal, but also *scylla.*
occurs in the Kumaon Himalayas, where Doherty met with it at elevations of 12—16 000 ft. He, however, regards *scylla* as a separate species, as it flies together with *brahminus* and is also said to show differences in the clasping-organs. The two forms are here united on Bingham's authority. — **brahminoides** *Moore* is the *brahmi-*
race of the collective species which is most commonly brought to Europe; it has a purer white median band, *noides.*
especially beneath, than *brahminus*, which occurs in the North-West Provinces, in Kashmir and Kulu, whilst *brahminoides* is confined to Bhotan and Sikkim. — **werang** *Lang* (vol. I, p. 122) is dusted and splashed *werang.*
with brown on the hindwing and exclusively inhabits the western slopes of the Himalayas.

A. swaha is the commonest species of the genus and it is curious that its interesting geographical variation has not been noticed by English authors. The typical subspecies **swaha** *Koll.* (vol. I, pl. 41 d upper *swaha.*
surface) was described from Kashmir, from whence I have it in my collection from elevations of 14—15 000 ft. Both sexes bear a relatively narrow light yellow median band, which, however, is always white on the underside of the hindwing. — In **garuna** *subsp. nov.* (94 c) this band is widened and is always yellowish parti- *garuna.*
cularly beneath. Common in Kulu, from whence by mistake its larva was also reported as being found on a wild blue iris, which is clearly incorrect. — **tellula** *subsp. nov.* I have received from the neighbour- *tellula.*
hood of Mardan, North-West Provinces; the band on the upper surface is about intermediate between *swaha* from Kashmir and *garuna* from Kulu, from both of which it may be distinguished by having the longitudinal band of both wings uniform pale straw-yellow, whilst in the other races the darker yellow of the forewing forms a sharp contrast to the whitish or quite white colour on the hindwing. Especially in the ♀ the under surface of *tellula* is also similarly white-banded.

A. padma, like *brahminus*, splits up into two geographical Himalayan races, of which **padma** *Koll.* *padma.*
(vol. I, pl. 41 f.) inhabits the north-western part and occurs in two generations, the first flying in May and June at the edge of oak- and rhododendron-forests on the peaks of the mountains at altitudes of 8—11 000 ft. A second brood appears in July and prefers the lower levels from 3—4000 ft. — **chumbica** *Moore* (94 c) is the *chumbica.*
westerly race, originally described from the Chumbi Valley in Native Sikkim, but recently received from Bhotan in large numbers. On the upper surface the longitudinal bands are pure white and scarcely half as broad as in *padma*, but beneath they are partially suffused with dark yellow. Flies August to September and at elevations of about 3—4000 m. — Examples from the North-West Provinces already show a darker colouring on the under surface and bear narrower bands than Kashmir specimens and are somewhat smaller; on the other hand **verres** *subsp. nov.* is considerably larger than the Kashmir form, and the under surface *verres.*
of both wings is lighter and more copiously irrorated with white. From June to August from 6—7000 ft., locally common in West China.

A. loha *Doh.* (vol. I, pl. 41 f), for the specific right of which its author strongly contends, is essen- *loha.*
tially different from *padma* and *chumbica*, to judge from examples before me from Bhotan and Sikkim, which, however, are not typical; from the former in the absence of the proximal white subapical patches of the forewing, from the latter in the much broader longitudinal bands. However, my Sikkim ♂♂ more nearly approach *chumbica* than *padma*, with which latter they nevertheless agree more in their large size. But perhaps it is only a seasonal form, either of *chumbica* or of *padma*. Doherty found *loha* in the Kumaon Himalayas in August—September from 3—4000 m. and Elwes observed it in Sikkim at Tonglo and Phallut at the same elevation in July above the pine-forests, where the butterflies flew vigorously round single trees, settled on the stems or occasionally on flower-heads. According to Leech it is common everywhere in West China.

A. saraswati *Koll.* (vol. I, pl. 41 d) can be most easily and certainly distinguished from all the known *saraswati.*
species by the rectilinear longitudinal band of both wings and by having the distal part of the hindwing beneath light brown, not black. The ♂♂ before me from Kulu differ quite considerably in having a much narrower white median area from the race discussed in the Palearctic part, which probably comes from Kashmir. *saraswati* shows a greater preference for the hotter and deeper valleys and apparently nowhere ascends above 2330 m. In Kulu, where it frequents thistle flowers, it occurs from July to the middle of October.

24. Genus: **Orinoma** *Gray.*

A monotypical genus, only containing one species of distinctive coloration, differing in the red-spotted cell of the forewing from all the known Satyrids. In neuration *Orinoma* somewhat approaches *Oeneis*, with which it has in common the weakly thickened costal, the long narrow cell and the short upper discocellular

of the forewing. On the other hand the short, broad cell of the hindwing differs from the *Oeneis* type and the straight middle and lower discocellulars point to a relationship with *Coelites*. The wing-contour is that of a Danaid.

damaris. **O. damaris** *Gray* (90 d) is beneath only somewhat paler and more copiously marked with yellow than above and the ♂♂ have narrower wings than the figured ♀. The butterfly is distributed from the Kangra district and the Kumaon Himalayas to Assam and Upper Burma and appears to have two generations, for in Nepal, Sikkim, Bhotan and Assam it is found in the autumn, whilst from Burma and Tenasserim it is reported from May. *damaris* apparently nowhere exceeds the altitude of 2000 m., is local and always
harmostus. rare. — **harmostus** *subsp. nov.* is a smaller race with lighter yellow spots and more delicate black lines on both wings and in spite of its small size with more extended yellow circumcellular patches on the hindwing. Tenasserim, taken there by me at about 1600 m. at Tandong.

25. Genus: **Rhaphicera** *Btlr.*

In habitus somewhat corresponding to our *Pararge*, it agrees with the preceding genus in not having the costal of the forewing thickened, but differs in the straight lower discocellular of the forewing, which is oblique distad, in the precostal of the hindwing arising at the point of origin of the subcostal (not distally to it) and the narrower cell of the hindwing, more recalling that of *Lethe*. Only 3 species described, which inhabit the Himalayas and western China and are everywhere rare.

satricus. **R. satricus** *Dbl.* (vol. I, p. 88, 32 c), distributed from the Kumaon Himalayas to the Naga Hills in Assam, was observed in Sikkim and Bhotan from 2000 m. to about 2500 m., where the butterflies fly rapidly and erratically, are fond of settling on wet and dirty places and also on shady or damp rocks and fly quite as freely in cloudy and rainy weather as on sunny days. The ♀ is extraordinarily rare, although it served as type. In western China occurs a smaller and darker race, which, however, is unknown to me in nature.

moorei. **R. moorei** *Btlr.* (vol. I, p. 88, pl. 32 c) somewhat recalls the European *aegeria*, is rather larger than this and smaller than *satricus*. In Sikkim it is very rare in the interior at altitudes of about 3000—3500 m. In the neighbourhood of Simla it occasionally occurs more commonly, flying there especially in August and even during the heaviest rains.

dumicola. **R. dumicola** *Oberth.* (vol. I, p. 88, pl. 32 c) is placed by Moore in his genus *Tatinga*. But as there are no differences at all in neuration from *Rhaphicera* this name must sink. — *dumicola* occurs commonly in some places in West China, rarely in Central China.

26. Genus: **Arge** *Hbn.*

There are no tenable grounds at all for giving any other name to this genus, so well-known as *Melanargia*, for the fine name of *Agapetes Billbg.*, adopted by Bingham, is about 4 years later than Hübner's name. In the Indian Region only one species has been met with, and this only on the borders of Burma and China.

A. halimede Mén. was discovered by an Indian forestry official in Burma. The form occurring there nearly agrees in markings with *montana Leech* from the Yangtsekiang, except that from Bingham's figure
leda. it does not seem to be larger than **A. leda** *Leech* (39 d), of which a somewhat darker form from Yunnan has
yunnana. been made known as **yunnana** *Oberth.* — **pasiteles** *subsp. nov.* is a race which connects *halimede Mén.* with
pasiteles. *lugens Honr.*, showing darker and broader black margins to the wings than Amur examples but not dusted over with brown. The under surface approaches that of *lugens*, but the ground-colour is pure white, without yellow admixture. As above broad, sharp, black submarginal bands stand out from the white ground. Shantung.

27. Genus: **Satyrus** *Latr.* (= Pararge *auct.*).

♂ The clasping-organs somewhat recall those of the genus *Erites*, the uncus is relatively short, thick, laterally angled, the lateral clasps slightly undulate or quite horizontal. The valve pointed like a sword, narrow, with long bristles. Jullien's rods have likewise been found in it, evidencing its relationship with the *Eumenis* and *Maniola* types. Forewing with the costal vein strongly inflated and the median less swollen. Precostal short, lower discocellular touching the point of origin of the middle median of the hindwing, by which a connection with the *Lethe* group of the Satyrids is established. Only 4 Indian species, which cannot be otherwise regarded than as Palearctic butterflies of Central Asia that have crossed the Himalayas and are slowly beginning to extend their range eastwards.

S. schakra *Koll.* (vol. I, pl. 45 e), the North Indian representative of our *maera* and like this one of the commonest butterflies from the western Himalayas to Sikkim. Flies from May to October. Prefers stony edges of streets. The larva is apple-green with pale yellow lateral lines. I have before me large series from Kashmir and the North-West Provinces which in colouring nearly correspond to those examples which form the transition from the northern *maera* to the South European *adrasta*. *schakra.*

S. maerula *Fldr.* (= laurion *Nicév.*) (vol. I, pl. 45 f.) approaches the preceding in size and colouring, but lacks the grey sexual spots of the forewing, and has the reddish ochre-coloured foreground of all the ocelli somewhat more extended. From the North-West Himalayas about Kunawur and Pangi, Mussourie. Occurring together with *schakra*, but rare. *maerula.*

S. menava *Moore* (= maeroides *Fldr.*) (vol. I, p. 135, pl. 45 f.) is a well differentiated species, the ♂ somewhat recalling our *hiera F.* in ground-colour, the ♀ recognizable by a broad, yellow-brown, obliquely placed patch in the apical part of the forewing, which is not composed of separate patches divided by black veins, but of one compact area. Upperside of the hindwing only with 2 instead of 3 or 4 ocelli. Underside darker, the distal longitudinal band straight, not angled as in *schakra* and *maerula*, and without whitish dusting in the distal-marginal area of the hindwing. **maeroides** *Fldr.* (vol. I, p. 135) is an aberration with a small cube-shaped spot below the apical eye-spot of the forewing. *menava* is local, flies from June to August. I have before me from Kashmir a fine series from an elevation of 14 000 ft. Also observed at Kunawar and at the Werang Pass at the same elevation. *menava.* *maeroides.*

S. kashmirensis *Moore* (vol. I, p. 134, pl. 45 c) is a very rare local form of the Turkestan *eversmanni*, than which it is much darker, particularly on the upperside of the hindwing. So far as is known it has only been found twice, at the Goolmurg Plateau at 2000 m. and at Pangi. *kashmirensis.*

S. masoni *Elw.* was formerly united with *Lethe*, but Moore quite correctly placed it near *Satyrus*, although the genus *Chonala* which he erected for it is not tenable. But *masoni* has nothing in common with *Lethe*, for not only the completely rounded hindwing separates it from the *Lethe* group, but also the thickened costal and median of the forewing. *masoni* agrees with *Satyrus* in all these differences, and likewise in its resemblance to *S. episcopalis Oberth.* (vol. I, pl. 45 b). Ground-colour black with the longitudinal band on the forewing somewhat broader and sharply defined proximally, and a moderately broad white distal border to the hindwing. Forewing further with two white subapical dots, of which the lower is somewhat larger than that of *episcopalis*. Under surface much as in *praeusta Leech* (vol. I, pl. 45 b), at least that of the hindwing, which is only somewhat lighter grey. Forewing with a reproduction of the broad oblique band of still more enlarged apical dots and with a large apical ocellus. — Hitherto only known from the interior of Sikkim. Elwes, whose collectors once brought him the species, suspects that it might be from the Chumbi Valley or from the border of Bhotan. I myself have only received 2 examples in the course of 20 years. *masoni.*

28. Genus: **Oeneis** *Hbn.*

That an almost Arctic genus like *Oeneis* should still be found on Indian territory is to be attributed to the enormous altitudes, which alone the butterflies inhabit, two species traversing the region from Native Sikkim to the border of Tibet. *Oeneis* is easy to distinguish from *Eumenis* by the long and narrow cell of the forewing and by having the costal vein only moderately thickened, but not swollen. Palpi and forelegs with extraordinarily long hairs.

O. pumilus is divided into two local races, of which the name-type **pumilus** *Fldr.* (vol. I, pl. 42 b) is found extremely rarely in the Kumaon Himalayas and in Kashmir. — *bicolor Seitz* (vol. I, pl. 42 b) is the local form discovered during the last English expedition to Tibet at Kambajong on the border of Sikkim, and has been sent to me from an elevation of 5000 ft. by Möller of Darjeeling. *pumilus.*

O. palaearcticus Stgr., from Central Asia, sends out an offshoot of smaller size to the borders of Tibet and into Native Sikkim, where occurs **sikkimensis** *Stgr.* (93 g), a form with somewhat darker under surface than *palaearcticus*; at Kambajong it flies together with *pumilus bicolor Seitz.* The upper surface as in *bicolor* (vol. I, pl. 42 b), only the ♀ shows paler yellow bands. *sikkimensis.*

29. Genus: **Lethe** *Hbn.*

Being structurally one of the most difficult genera to deal with, *Lethe* has met with the fate of being split up unnecessarily into numerous fragments (Moore) and has recently served as a receptable for the most heterogeneous groups of species (Bingham). A division in some degree natural must consequently lead to reducing an accumulation of some 15 generic names, but on the other hand also to breaking up a too comprehensive collection of species. Bingham has already employed a very happy grouping, founding his two subdivisions on the presence or absence of modified scales in the ♂♂. This, however, unfortunately

cannot be used for the ♀♀, but otherwise affords a safe guide. A reliable indication is furnished by the shape of the wings, whether rounded or with tail-appendages, the more or less pronounced swelling of the costal vein and not least by the fact that in whole series of species the lower discocellular of the hindwing does not touch the furcation of the upper and middle median, but the upper median vein, which is then separated by a broad stalk from the middle median. But all the members of the *Lethe* group in common have the costal and subcostal of the forewing coincident for half their length. The secondary sexual characters are very various; they may be present on both wings or only on the fore- or only on the hindwing. But in no species have hair-pencils yet been detected, which play so essential a part in the grouping of the Mycalesids, never even tufts of long hairs. The clasping-organs are sharply differentiated in the separate groups, thus in true *Lethe*, as in *Melanitis*, the lateral clasps of the uncus are apparently absent, whilst in *Hermias* they are not only distinctly present, but also bear a very broad, horn-shaped point. The valve may be narrow and very long and simple (*Lethe*) or short and with dorsal protuberances (*Hermias*). Larva and pupa are described in vol. I (p. 82); they are only known of about four species, notwithstanding the accessibility of their food-plants — bamboos and other grasses. As a rule they are mountain butterflies and the traveller encounters one species — *L. rohria* — as a living altimeter in the Sunda Islands when he approaches 1200 m., as it never descends lower, but immediately appears where the cool mountain breeze begins to be felt. All the other species love the shade and are most lively at early morning or in the evening twilight. The butterflies rest with folded wings in the bamboo thickets or on blades of grass, but rarely, like *Mycalesis*, on the ground. The head-quarters of the genus is continental. Nearly 50 species of the *Lethe* group are found within the limits of the Indian Empire, but Borneo and Java have seven, Lombok three, Celebes and the Moluccas only one species. The genus has not reached the Papuan region and Australia in its eastward course. Altitudes of 2—3000 m. suit them best, only one species ascends to 14 000 ft. (*maitrya*). According to my observations in Hong-Kong one species (*arete*) smells extremely strongly of vanilla.

Group Sinchula *Moore*.

The most insignificant forms of the genus. Hindwing rounded, without distinct point at the lower median. The lower discocellular does not touch the fork of the upper and middle median, but arises distally to it. Costal distinctly cystose. ♂ without sexual spot on the upper surface.

sidonis. **L. sidonis** *Hew.* (vol. I, p. 85, pl. 31 d upper surface and vol. IX, pl. 97 c under surface) breaks up into two seasonal forms, of which Hewitson knew and described that of the wet season (97 c), of which *gelduba.* we reproduce the under surface. The dry-season generation **gelduba** *form. nov.* is as usual smaller and is above paler with brighter bronzy sheen. The anterior ocelli of the hindwing beneath are partially suppressed, whilst the posterior are reduced. Likewise the grey-blue median stripes are frequently absent, particularly in Bhotan examples. In Assam occurs a local form, which is larger and beneath more brightly coloured. According to Elwes *sidonis* is one of the commonest *Lethe* of Sikkim, where it occurs in the forest zone from 4—8000 ft. from April to November, especially on the paths, and either remains on the ground or on lower vegetation. Sikkim, Bhotan; Assam.

vaivarta. **L. vaivarta** *Doh.* nearly approaches the preceding and might be regarded as a western race of *sidonis* if Doherty had not stated that the clasping-organs are different. Judging from Moore's figure of the typical specimens the most essential distinguishing character consists in the longitudinal bands of the forewing beneath being broader and yellow instead of violet and the eye-spots of the hindwing larger and showing through above. The dry-season form was discovered by Doherty in the Kumaon Himalayas, but the species extends further to the west; for it is also recorded from Kangra, in southern Kashmir. Larva light green with two horns on the head and pale longitudinal and transverse stripes. It lives on the mountain bamboo Arundinaria falcata Nees. Pupa green, more rarely red-brown, short, with two tubercles on the head and whitish sides and whitish speckles on the ventral side.

nicetella. **L. nicetella** *Nicév.* (97 c). Upper surface unicolorous black-brown with slight bronzy reflection, hindwing with the eye-spots of the under surface showing through. In the dry-season form some of the ocelli on the underside of the hindwing are blind and the forewing shows grey-yellow patches in the distal part. In July-August at Tunglo from 7 to about 9000 ft. on shady or wet places, sometimes in thousands. The ♀, however, is very rare. Not yet observed outside of Sikkim.

siderea. **L. siderea** *Marsh.* (vol. I, p. 85) is a rare Sikkim butterfly, only once taken in the interior of the country at 7000 ft. in the rainy season. ♀ still unknown. Under surface of the hindwing very near to *nicetella*, but with longer stripes and the ocelli with brighter orange-coloured bordering. According to Leech also found as a rarity in West China.

L. nicetas *Hew.*, of about the size of *sidonis*, is easy to recognize by the broad yellow postdiscal bands on the underside and a whitish obliqne band of the forewing, both of which show through above. Moreover, the eye-spots of the hindwing are of unequal size and transparent. Rather rare, observed at Daling in May and June, but distributed from Sikkim to Kulu, flying there even in October and occurring everywhere from 1000 to 2500 m. in dense forests. *nicetas.*

L. maitrya *Nicév.* (97 c) is the species of the group most commonly brought to Europe, which is met with, particularly in July and August, in enormous numbers, especially at the border of Sikkim and Neapel. The type came from the North-West Himalayas and specimens from there are somewhat larger than the Bhotan example figured. According to Elwes *maitrya* always flies in company with *Zophoëssa jalaurida* at altidutes of 3— about 4000 m. *maitrya.*

L. visrava *Moore* (= deliades *Hew.* and figured at 97 c under the latter name) is a very rare species, the ♀ of which has the hindwing almost entirely white and the forewing likewise white to the cell. The hindwing is adorned with large, frec black ocelli, which beneath are broadly margined with yellow. Moreover, in the ♀ the terminal border of the hindwing is reddish yellow. The ♂ only differs on the under surface in having the white area on both wings more extended and more sharply defined. Flies in June. Sikkim, Bhotan. *visrava.*

L. insularis *Fruhst.* (97 c) approaches the Chinese *procne Leech* (vol. 1, pl. 32 b), from which, however, it differs in the more rounded wings, the smaller size and the almost vertical yellow-brown submarginal band of the forewing above. Beneath *insularis* is characterized by a beautiful moss-green tinge on the basal part of the hindwing, which does not show on the figure, and especially by the twice interrupted white median band, which runs from the costal to the anal angle and is gradually narrowed. Formosa, at about 4000 ft., apparently rare. *insularis.*

The following Palearctic species belong to *Sinchula*: L. *violaceopicta Pouj.* (= callisto *Leech*) from West China (vol. 1, p. 85, pl. 31 c); *L. titania Leech* (vol. 1, p. 85, pl. 31 c) from West China; *L. helle Leech* (vol. 1, p. 37, pl. 32 b) (hitherto regarded as a *Zophoëssa*), West China; *L. procne Leech* (vol. 1, pl 87, pl. 32 b), for which the same genus was accepted, West China. — *L. callipteris Btlr.* (vol. 1, p. 86, pl. 31 e), one of the most beautiful species known, distributed in Japan from Shikoku to Yesso; Moore created the genus *Harima* for it.

Group Kerrata *Moore.*

Structure and wing-contour as in *Sinchula*, but the forewing bears in the median area narrow, elongate patches of shaggy androconia.

L. tristigmata *Elw.* (97 d). Upper surface grey-brown with transparent bands and ocelli and the sexual spot already mentioned. Very rare, hitherto only known from Sikkim, where it flies in July near the borders of Nepal at elevations of 9—10 000 ft. The ♀ was first discovered in 1888 by Möller in Native Sikkim. — **lyncus** *Nicév.* is in Bingham's opinion only a paler form of *tristigmata*: according to the figure it is rather a rainy-season form, but in the subapical spots of the forewing there are differences which perhaps justify a separation, as *lyncus* bears a short white band instead of five isolated dots; the basal part is also darker, the ocelli more fully bordered with yellow. Nicéville compares it with *ocellata Pouj.*, which it decidedly nearly approaches. Sikkim, only two ♂♂ from Native Sikkim known, which were collected in July and August at elevations of 7—10 000 ft. *tristigmata.* *lyncus.*

Two Palearctic allies: *L. nigrifasciata Leech* (vol. 1, p. 85, pl. 31 e), of which there is a smaller local race, *fasciata Seitz*; West China. — *L. ocellata Pouj.* (= simulans *Leech*) (vol. 1, p. 85, pl. 31 c); West China.

Group Magula *nom. nov.*

Structure as in *Sinchula*. Hindwing, however, with distinct tail-appendage at the lower median. No sexual spots. The few species belonging here have been hitherto united with *Zophoëssa*, from which they can be at once separated by the different position of the lower discocellular, which is formed as in *Sinchula*. But this group has as little claim to subgeneric rank as *Kerrata*.

L. jalaurida, named from the Jalauri Pass in Kulu, where Nicéville met with it in large numbers on the red flowers of a Persicaria in the midst of dense forest at elevations of between 6—8000 ft., in company with *L. maitrya*. **jalaurida** *Nicév.* (vol 1, p. 87) occurs especially in the West Himalayas, but what we meet with as such in collections belongs to **elwesi** *Moore* (vol. 1, pl. 32 c, as *jalaurida*), which differs from *jalaurida* in the paler colouring and the more sharply defined silver bands on the under surface. According to Elwes this form flies at the Nepal frontier of Sikkim from 9—12000 ft. in July and August in open places in woods, rapidly circling round even in dull and rainy weather and assembling in small groups where there is any filth to attract them. Sometimes they also rest on bamboo and on rocks, particularly in damp weather, where they can be taken off with a bottle like moths. — **gelduba** *subsp. nov.* is a local race occurring sparsely in western *jalaurida.* *elwesi.* *gelduba.*

China, of a dark olive shade above and bearing on the under surface a double instead of single transcellular stripe, but no fine silver line on the lower median such as adorns *elwesi*.

moelleri. **L. moelleri** *Elw.* (97 d), somewhat larger and above with somewhat broader yellowish bands and larger ocelli than *elwesi*, occurs at the same localities and has not yet been met with outside Sikkim.

atkinsonia. **L. atkinsonia** *Hew.* (97 d), the most highly coloured species of the group, bears above large dark ochre-coloured bands and spots. It is rather rare and was discovered at the Senchal Hill, the locality of *Teinopalpus imperialis*, and afterwards also by Elwes on the road to the hospice of Tonglo, where it occurs in July and August from 8—9000 ft., and when startled up, takes refuge in the dense thickets.

Group Zophoëssa *Dbl.* (= Putlia *Moore*).

With this group of species we reach *Lethe* proper, the fundamental character of which is that the lower discocellular touches the furcation of the two medians. It was formerly thought that *Zophoëssa* should be treated as a separate genus, on account of the somewhat longer terminal joint of the palpus, which, however, varies greatly, and the more strongly swollen costal of the forewing. But the latter character certainly rests on an error, for in no *Lethe* are the two principal veins less inflated than in *sura*, the type of *Zophoëssa*. Hence Bingham was right in merging it, and if it is here treated as a subgroup it is on account of the longer cell of the forewing, which is probably at the same time narrower than that of any true *Lethe*. All the species bear long tails, which only in a few Palearctic forms are somewhat less developed. Sexual spots are mostly present.

baladeva. **L. baladeva** *Moore* (97 d). Upper surface coffee-brown with the longitudinal bands of the under surface showing through. Hindwing with black eye-spots of unequal size, of which the last sometimes shows a white pupil. The type came from Sikkim, where the species is rather rare on the Tonglo road in June from 7—9000 ft.
aisa. The ♀ is especially scarce, somewhat larger and paler brown. — **aisa** *subsp. nov.* is the local race discovered by Doherty in the Kumaon Himalayas, which is not only darker than Sikkim specimens, but beneath also bears much narrower silver bands. Flies in June at the same elevations as *baladeva*.

ramadeva. **L. ramadeva** *Nicév.* (97 d) above resembles *baladeva*, but is traversed by broader yellow bands, which show through from the underside. The ocelli of the hindwing materially larger and a broad red-brown area before the anal angle. Extraordinarily rare, only recorded as yet from Sikkim and Bhotan, where it flies from July to August.

andersoni. **L. andersoni** *Atk.* is an interesting and hitherto very rare butterfly, of which only four examples are known, two of which are in the British Museum collection and two in the Museum in Calcutta. Upper surface brown with yellowish longitudinal bands on the forewing and small round ocelli on the hindwing. Hindwing rather narrow, under surface so similar to that of *L. argentata Leech* (vol. 1, p. 87, 32 a) from West China that they are probably both branches of one collective species. Bhamo in Upper Burma and South Yunnan.

goalpara. **L. goalpara** *Moore* (99 a), essentially larger than either of the preceding *Zophoëssa*, is above scarcely distinguishable from *sura Dbl.*; black-brown like that species, with a brown longitudinal band and five large black eye-spots on the upperside of the hindwing. On account of the peculiar, washed-out yellow-grey under surface, however, it cannot be confused with any other species. It was formerly regarded as rare, but Nicéville reports that the natives sometimes bring in thousands of specimens. Flies from the end of July to No-
narkunda. vember at 2—3000 m. Distributed to North Assam. — **narkunda** *subsp. nov.* is a geographical form from the western Himalayas with the under surface suffused with darker brown; known from the Narkunda Wood near Simla. Between Simla and Sikkim *goalpara* has not yet been observed.

L. dura is the most widely distributed *Zophoëssa*; formerly known from Bhotan to Tenasserim, it was found by me in Tonkin, Sauter has discovered it in Formosa, and *dautensis Semp.*, from the Philippines,
gammiei. must probably also be referred here. — **gammiei** *Moore* is the western branch race, described from Bhotan, paler than typical *dura* from Tenasserim, the distal margin essentially lighter. Under surface lighter with blue-pupil-
dura. led ocelli. Bhotan, September, rare. — **dura** *Marsh.*, above velvety brown, with very narrow grey-brown distal margin to the wings. Hindwing with small ocelli. Differing from *sura* in the sexual stripes of the forewing not standing out distinctly and in having the eye-spots of the hindwing mere dots instead of one to two mm. in breadth.
mansonia. Karen Hills, Burma and Tenasserim. — **mansonia** *subsp. nov.* (99 a) is a darker local race, almost without light distal border on the upper surface of the wings and mostly with the submarginal dots of the hindwing entirely absent. The under surface bears more sharply defined bands and the ocelli are bordered with brighter yellow. Tonkin, Manson Mountains at about 4000 ft. in April. A woodland butterfly, settling on lower vegetation.
moupinen- — **moupinensis** *Pouj.* (vol. 1, p. 86, pl. 32 a), known from West and Central China, judging from Leech's figure
sis. shows much smaller eye-spots, only slightly bordered with reddish, on the underside of the hindwing. — Finally,
neoclides. **neoclides** *Fruhst.* is a prominent island race, recognizable at once by a very broad whitish grey subanal area on the upperside of the hindwing, in which are placed five small, isolated, blind eye-spots which are nearly obsolete but still just perceptible. Hindwing further with a fine reddish grey anteterminal line. Under surface

with very broad brown longitudinal bands, extremely washed-out grey markings, and indistinct eye-spots with extended blue pupils. In size *neoclides* is about midway between *mansonia* and *sura* from Assam. Formosa, from about 4000 ft., apparently very rare, as I have only received one ♂. — **daatensis** *Semp.*, only known to me *daatensis.* from Semper's figure, which agrees in size with *mansonia*, but shows broader black-brown bands and the under surface of the wings more copiously decorated with blue. Only one ♂ yet found, at the peak of Monte Datà from 2250 m., flying in August. North-West Luzon.

L. sura *Dbl.* (99 a), the largest species of the group, is regarded by Bingham as identical with *dura* *sura.* *Marsh.*, which is not improbable; but as both forms occur together in Bhotan and Burma I keep them separate. If, however, they are really identical, then *dura* and *mansonia* must be regarded as dry-season forms, as well as *gammiei Moore*. But I have before me in both sexes from Sikkim evident dry-season forms of *sura*, which have nothing in common with *dura*. *sura* is met with in Sikkim in the woods from June to November at about 8000 ft., either resting on the path or on low growths. When started up the butterflies settle on tree-trunks, where they are difficult to distinguish in the darkness. Distributed from Bhotan to Assam and Upper Burma, where Doherty found it still common at Bernardmyo at 2000 m.

Group Lethe.

Only distinguishable from the preceding group by having the cell of the forewing always somewhat broader, and as a rule also shorter. The length or shortness of the cell, however, differs from species to species. Clasping-organs similar to those of *Melanitis*. Uncus without lateral clasps. — Valve very long and narrow, distally with the tip curved down without dorsal protuberance. Saccus broad at the base.

a) Without sexual spots.

L. rohria is a relatively small, widely distributed species, which was already known to Fabricius and described by him from India. Aurivillius thinks the name *rohria* ought to be transferred to the South Indian *dyrta Fldr.*, which may be quite justifiable, but the example of the Palearctic part is followed here, in order not to suppress the well-known name and introduce discrepancies into the text. — **rohria** *F.* (vol. 1, p. 84, pl. 30e) *rohria.* covers the whole of India from the Kumaon Himalayas, flying at elevations of 1200—7000 ft. and frequenting roads and the edges of woods. According to Nicéville the spring generation is distinguished by the brighter colour of the under surface; from the wet-season specimens before me I should describe the latter as larger and with more extended and more glossy whitish violet bands beneath. — **gambara** *subsp. nov.* is the Assam *gambara.* race, which perhaps occurs in the same form also in West China, and which may be distinguished from Sikkim examples by the larger size, the brighter white, more band-like subapical spots on the forewing above and by having the ocelli on the underside of the hindwing larger and especially with more intensive, broader, and brighter yellow bordering. Wood-Mason already called attention in 1887 to the delicious vanilla odour which is emitted by the ♂♂, a fact which likewise struck me in 1899 in Hong-Kong. Nevertheless the bodies taste extremely bitter on the tongue. — **apara** *subsp. nov.* is a degenerate form; examples of both sexes which belong here are not only *apara.* smaller, but the white oblique band of the forewing is also narrower, the eye-spots of the under surface become smaller and the violet-white longitudinal bands begin to disappear. Tenasserim from 4000 ft.; Tonkin from June to August from 300—600 m.; Hong-Kong; Hainan. — **enima** *subsp. nov.* (97 a) inhabits Sumatra and is *enima.* at once distinguished by having the white band of the forewing almost twice as broad and the ocelli only minute and bordered with yellow-grey instead of whitish violet. ♀ moreover strikingly pale red-brown. According to Martin the ♀♀ of this species are not much rarer than the ♂♂ and according to Hagen large numbers of *enima* enliven the Battak Plateau in the interior of the island, forming quite a feature of the landscape, with its savannahs overgrown with lalang grass. — **godana** *subsp. nov.*, smaller in size, with a more yellowish, very narrow *godana.* band on the forewing and reddish instead of black under surface. The eye-spots only with dull and obscure yellow-grey bordering. Very common in Java, where it is the first butterfly to meet the traveller on his ascent of the mountains, when he has passed the first 1000 m. In Mussourie, India, *rohria* occurs in two generations, first in April and May, and again August to October.

L. europa, already discussed in the Palearctic part, is one of the few *Lethe* which descend to the alluvial plains, a true village butterfly and to be found wherever there are bamboo hedges. Fabricius gave America as habitat of his type, which Butler was the first to correct, substituting Java, where the butterfly is indeed very common. If then the Javan branch-race is regarded as the name-type, some of the offshoots of the species occurring outside the Malay islands must be separated. But the ♀♀ of all the forms have in common a slightly broken, rather broad white band and nearly wedge-shaped ocelli, pressed flat, as it were, on the underside of the hindwing. The continental Indian race may be separated as **niladana** *subsp. nov.*; the ♀ is marked nearly *niladana.* as *nudgara*, but is smaller. Distributed from the Kumaon Himalayas to Burma, known everywhere as a lover of the shade and also of sweets. In Siam I took a strongly aberrant form, which probably occurs exclusively

gada. in the rainless period, in which season I collected it. — **gada** *form. nov.* is above easily recognizable by the larger yellow-grey patches and the broader yellow-grey distal border of both wings, which is very striking, especially as the examples are relatively of small size. ♀ with narrow white oblique band on the forewing. Under surface of the forewing with almost white, instead of yellowish subapical transverse bands. Siam and Tonkin in January
ragalva. and again from August onwards. — **ragalva** *subsp. nov.* is an absolute contrast to the preceding, forewing beneath traversed by a dark brown-yellow oblique band. Under surface of the hindwing likewise altogether darker,
nudgara. ocelli smaller, margined with dingy brown. Larva on bamboo. South India, Karwar. — **nudgara** *subsp. nov.* (96 c) is the largest branch race before me, at the same time bearing also the broadest white band of the forewing
tamuna. in the ♀♀. Andamans. Common near Port Blair. — **tamuna** *Nicév.* is a rare race from the Nicobars, only one ♀ as yet discovered, showing an ochre-yellow, instead of white band on the forewing (perhaps discoloured by moisture ?) but the form also differs further in having the band of the forewing distally more broken up, the
europa. yellow distal border broader and the median band of the hindwing more strongly angled. — **europa** *F.* (96 d) is the Macromalayan subspecies, in addition to the large islands also from Bawean and Nias in my collection, likewise known from Kangean. — Essentially different is the form from the island of Engano, which I would here
kumara. call **kumara** *subsp. nov.* The ♀ is characterized above by the white band of the forewing being only inappreciably broken, and hence almost rectilinear, and the apical ocellus of the hindwing in both sexes is almost twice as large as in Javan specimens and in the ♀ exceptionally distinctly margined with pure white. Rare, only found in April. — Towards the east *europa* first changes appreciably on Lombok. The form from this island is here introduced
mahamaya. as **mahamaya** *subsp. nov.* (96 d), ♀ characterized above by having the white transverse band rapidly narrowing posteriorly and strongly incised distally and beneath by the yellow tinge, especially on the forewing, which is not brought out correctly on the figure, accompanied by a weakening of the black cell-dots. Lombok, from the
pavida. coast up to the plateau of Sambalun (4000 ft.). — **pavida** *Fruhst.*, from Formosa, is a smaller and darker reproduction of the continental form, under surface easily recognizable by the less developed white or yellowish
alaca. longitudinal bands. Common on the whole island, as also on Hainan. — **alaca** *subsp. nov.* is the branch from the Philippines, which I have before me only from Palawan, but which probably also occurs identically on the other southern Philippine Islands. According to Semper *europa* flies there all the year round. *alaca* is beneath easy to distinguish by the unusually large and strongly elbowed white median band of the hindwing, which is
beroë. proximally bordered by very small ocelli. — **beroë** *Cr.* is the Chinese representative of the collective species, and is not known to me in nature, but according to Cramer's figure is distinguished by very large and uniform
cevanna. black ocelli on the hindwing of the ♀♀. South China. — **cevanna** *subsp. nov.*, judging by ♀ examples from Mindanao in coll. Staudinger, is the largest of all the insular races; it shows signs of island malanism in having the oblique band of the forewing narrow and appreciably darkened with yellowish.

L. arete, which by earlier authors was united with *europa* or confused with it, is doubtless the eastern representative of the western *L. europa*, but can stand as a species on account of the different shape of the wings and the round instead of apical ocelli of the hindwing. At the same time it must be admitted that the hitherto unknown South Celebes form presents in a measure a transition from *arete* to *europa mahamaya Fruhst.*
arete. from Lombok. **arete** *Cr.* (96 d), the name-type, inhabits the South Molucean islands of Amboina, Ceram and the Uliassers and is also in my collection from Buru. The chief difference from *europa* consists in the absence of the yellowish or white oblique band on the underside of the forewing, of which only a small vestige remains at the costal margin. ♀ above as in *europa* with a very broad white transverse band on the forewing, which is basally
arcuata. excurved far proximad between the medians. This is most pronounced in **arcuata** *Btlr.*, from North Celebes, whose ♀ differs from that of *arete* in its larger size and the quite thin median band on the underside of both
anatha. wings. Collected by me at Toli-Toli and the adjacent islet of Lutungen, in November and December. — **anatha** *subsp. nov.* is smaller than *arcuata*, above darker blue-grey, the subapical spots of the forewing obsolescent, all the ocelli of the under surface more compressed, but with strikingly broad, bright, glossy whitish violet
advipa. bordering. Sula Mangoli, collected by Doherty (October, November). — **advipa** *subsp. nov.* occurs on the North Moluccas: Batjan, Halmaheira and Ternate; it is always smaller than *arete* from Amboina, and the forewing is traversed by a narrower white band. Ocelli on the underside of the hindwing essentially smaller, but
velitra. more than twice as broadly margined with light earth-brown. — **velitra** *subsp. nov.* inhabits Sangir, approaches *arcuata* from Celebes, is almost as large as this, but bears much narrower white subapical bands in the ♀♀ than
nagaraja. *arcuata* and even *advipa*. — Furthest removed from the *arete* type is the hitherto unnoticed South Celeban **nagaraja** *subsp. nov.* ♂ above more distinctly spotted with yellowish white than *arcuata*, smaller, beneath with the ocelli as compressed as in *anatha*. ♀ differing not only from the ♂ but also from all the other *arete* races in having the ground-colour above light grey and beneath light, washed-out yellow-brown. Forewing with a narrow whitish band, strongly broken beyond the cell, ocelli of the hindwing also above conspicuously bordered with yellowish brown. Pupils of the ocelli on the under surface yellow, not brown as in *arcuata*, and beautiful red-brown longitudinal bands standing out in vivid contrast to the pale ground-colour. South Celebes, collected by me from the neighbourhood of the waterfall of Maros up to 1000 m. at the peak of Bonthain.

L. dyrta, probably the *rohria* of Fabricius, is one of the few species of which the earlier stages are known. The species is more widely distributed than was formerly supposed and its insular and local variation

has not hitherto been noticed. — **dyrta** *Fldr.* (vol. 1, pl. 30 d), described by its author from Bengal, is the North Indian branch of the collective species, occurs in Sikkim only in the hot lowlands, extends westwards to Kashmir and eastwards to Burma, and ascends in the Himalayas to 5000 ft. In Tonkin I observed two seasonal forms, one in April, at elevations of about 1000 m., with uniform grey, quite dull under surface, belonging to the dry season, and the rainy-season form with distinctly defined, silvery, violet-white bordering to the ocelli and longitudinal bands of the same colour (June—July). — **neelgheriensis** *Guér.* (96 d), from South and Central India, ascends in the Nilgiris to 7000 ft. Larva on bamboo, very long, slender, head and anus with long, sharp points. Light green with darker dorsal and lateral stripes. On Ceylon the larva was also found on grasses. — **yoga** *subsp. nov.* is the sharply differentiated island form of the upper surface of which Moore has given a very characteristic figure in Lepidoptera Indica; we represent the under surface at 97 b. ♀ easy to distinguish from the preceding race by the band of the forewing being broken up into three large, rounded, widely separated spots, whilst in *neelgheriensis* and all the other *dyrta* races it always traverses the forewing as a continuous broad band. *yoga* is further characterized by the darker under surface of the wings in both sexes (a manifestation of island melanism) and by the yellower, much narrower and more angled band of the forewing in the ♀. Ceylon. — **permagnis** *subsp. nov.* is the race from southern China, already mentioned by Leech from Foochow, and also known from Amoy. Whether examples from West and Central China are identical with it is still doubtful. The ♀ differs from that of *dyrta* from Tonkin in its larger size and in having the oblique band of the forewing yellowish instead of white. Under surface washed-out grey without distinct violet-white bordering to the ocelli, on which account I suspect that the ♀ type before me was collected in the dry season. Foochow. — **daemoniaca** *Fruhst.* is the branch from Formosa, which is somewhat smaller than *permagnis*, but nevertheless surpasses continental Indian examples. ♀, particularly beneath, with yellowish band and relatively small ocelli. Formosa, common on the whole island up to 1300 m, and also in Hainan. — **anunda** *subsp. nov.* is the charming and well separated island race recorded from Java since Horsfield's time, but not adequately noticed; it may be recognized by the delicate red-brown or chocolate-coloured under surface in both sexes and by the much smaller ocelli on the underside of the ♀, which are scarcely appreciably bordered with yellow. In my collection only from East Java and Bali, but it will certainly also occur in the west and probably in Sumatra. — **sambaluna** *subsp. nov.* (97 b) is the most easterly offshoot of the collective species; in contrast to the Javan form the under surface is grey and more washed-out than in continental examples. Above both sexes bear pure white subapical patches and the band of the forewing is more frayed at its proximal and distal edges. Locality the Plateau of Sumbalun on Lombok, at about 4000 ft., collected by me in April 1896. The form flies at the edge of the woods.

dyrta. *neelgheriensis.* *yoga.* *permagnis.* *daemoniaca.* *anunda.* *sambaluna.*

L. drypetis is one of those zoogeographically interesting species which are peculiar to southern India and have spread from there to Ceylon. — The name-type **drypetis** *Hew.* (= embolima *Btlr.*) (97 a misprinted *ebolina*) inhabits Ceylon, where it is met with in bamboo hedges, not very commonly. It is very local and as a rule does not occur below 1000 m. ♂ above unicolorous brown, ♀ with white oblique band, darkened into yellow at the margins, and beyond the cell twice slightly interrupted. Hindwing with three black spots, which are anteriorly and distally margined with light brown-yellow. Under surface of the ♂ similar to *daretis*, but without the yellow band of the forewing. Larva as in *neelgheriensis*, but more brightly coloured, with a lateral, pale-edged red stripe. Pupa pale green with a horn on the head and another on the breast. — **todara** *Moore* (97 e as *drypetis*), is the South Indian branch of the species, which only differs slightly from the Ceylon type. ♀ above and beneath lighter brown-yellow, transverse band of the forewing somewhat narrower, more regular, under surface with the brown shading less extended. South India, flying from May to September, and ascending to 4000 ft.

drypetis. *todara.*

L. daretis *Hew.* (97 a) is a delicate species, endemic in Ceylon and found nowhere else. ♂ above with three yellowish subapical patches. Hindwing with some black dots. ♀ with a beautiful yellow oblique band, consisting of four loosely connected patches, and two rounded yellow subapical patches on the forewing. Hindwing with yellowish submarginal area, in which are placed 5 ocelli of unequal size. On the under surface the bands are reproduced and the hindwing is lighter grey-brown, otherwise identical with that of the ♂. *daretis* flies all the year round, and is one of the few butterflies which occur at elevations of 7000 ft. on the Horton Plains. Dr. Seitz took it at Nuwara Elya. The ♂♂ are fond of resting on the upper branches of low forest-trees and fly round their tops in the sunshine.

daretis.

L. insana, a common species, distributed over the whole of the Himalayas and western China to Formosa, is better known under the name *dinarbas*. — **insana** *Koll.* (♂ = hyrania *Koll.*), described from Kashmir, is a relatively small highland form with grey-brown upper surface, the ♀ distinguished by a strikingly broad, sharply defined white transverse band on the forewing. ♂ beneath without red-brown patches on the forewing or silvery submarginal area on the hindwing. The butterflies are fond of shade, being met with at the foot of high rocks which cast a shadow all day long. Kashmir, Kulu, Mussourie and Kunawur. In Mussourie two generations occur, the first from April to June, the second in October. Larva on Arundinaria falcata Nees, the „Hill Bamboo" of the English. Green with a yellow dorsal spot, the head as usual very pointed; pupa sometimes green, sometimes brown, very similar to that of *drypetis*, only shorter. — **dinarbas** *Hew.* (97 a), judging from Hewitson's figure, seems to be founded on examples of the dry-season form and such specimens from

insana. *dinarbas.*

Assam in my collection agree best with its author's figure. Our figure shows the rainy-season form from Sikkim from the under surface. Not rare at 7—9000 ft. in the primeval forests of Sikkim and Assam. Doherty took *brisanda.* it also in the Naga Hills, from June to September. — **brisanda** *Nicév.*, described from Bhotan, is an extreme rainy-season form, easily recognized by the somewhat larger ocelli, a broader violet-white longitudinal band on the forewing and a metallic distal area on both wings. Hitherto only recorded from Bhotan, whence of *baucis.* late years it has been commonly brought to Europe. — **baucis** *Leech* (vol. 1, p. 84, pl. 30 c) must be regarded as the West Chinese local race. Band of the forewing narrow, rather sharply defined. ♀ with somewhat rounder *procris.* wings than its Indian allies. — **procris** *Leech* is a small aberration of *baucis*, and according to two examples taken by me in April at about 4000 ft. in the Mauson Mountains in Tonkin, which agree with Leech's figure, *formosana.* should probably be regarded as a product of the dry season. — **formosana** *Fruhst.* is a very small island race, about agreeing in size with the dry-season form from Sikkim; under surface, however, without the red-brown areas of *dinarbas* and with very small ocelli. From Mt. Morrison from 5000 ft., September, Formosa, rare.

margaritae. **L. margaritae** *Elw.* (97 b) is probably the largest *Lethe*, hitherto only known from Bhotan, from whence it is brought by the native collectors. Upper surface somewhat darker brown than beneath with complete reproduction of the yellowish grey bands and ocelli. The very rare ♀ is especially beautiful, showing a white oblique band on the forewing, a white median band on the underside of the hindwing and very large ocelli with yellow-brown bordering.

naga. **L. naga** *Doh.*, discovered by its author, who, however, only succeeded in finding one ♀ at the upper boundary of Assam. It approaches the ♀ of *philemon* (97 b), but bears on the forewing a white subapical band of uniform breadth running to the anal angle and on the underside of the hindwing a curved, whitish violet *philemon.* band reaching to the middle of the wing, which is absent in *philemon.* — **philemon** *Fruhst.* (97 b), from Than-Moi, in northern Tonkin (June—July), bears in the ♂ a distant resemblance to *lanaris Btlr.* (vol. 1, pl. 30 b), but the wings are more rounded and the ocelli on the underside of the hindwing, especially the apical one, are considerably larger. The number of ocelli on the underside of the forewing varies from 2 to 4 and the whitish violet bordering to the eye-spots of the hindwing is sometimes somewhat less intensive than on the figure. Very probably *philemon* occurs also in Yunnan, which may well be the true home of the butterfly, as I suspect it has spread from China to Assam and Tonkin.

b) With sexual spot on the fore- or hindwing or on both alike.

L. minerva is distinguished by the large black androconial patch of the forewing and the wide sexual dimorphism. Previously only known from Macromalayana, the species was also discovered by me in Lombok, *minerva.* the most easterly outpost of Micromalayana. — **minerva** *F.* (= arcadia *Cr.*, caumas *Godt.*) (98 a). All the names refer to the race from Java, where the butterfly is not rare either in the east or west, and comes both to fallen fruit and the same used as an artificial bait, appears nowhere to ascend above 2000 ft. Seasonal influences act upon it in so far as that examples of the dry season are smaller and a little paler than those of the rainy period. In general *minerva* is extremely constant, and the specimens collected by me in Lombok are only very slightly richer red in the ♂ and with somewhat narrower bands in the ♀. In Borneo *minerva* does not occur, and even *tritogeneia.* in Sumatra it is of rare occurrence. Doherty found it on Bali. — **tritogeneia** *subsp. nov.* is distinguished by the more extended and lighter red subanal region on the upper surface of the ♂♂ and the larger black patches of the ♀♀, and differs beneath in the darker ground-colour. Tenasserim, from January to November. Everywhere in Burma, but only sparingly. According to Distant's figure examples from Perak belong rather to *minerva* than *tritogeneia*; there too the species is rare.

dynsate. **L. dynsate** *Hew.* only occurs in Ceylon and is unknown to me in nature. ♂, according to the figures before me, brown above, with large, elongate sexual spot, formed as in the Euploids, between the lower median and submedian, two yellowish apical dots and on the hindwing five medium-sized black ocelli. ♀ with broad white oblique band on the forewing, a narrow median band, curved first distad and afterwards towards the base, and white bordering to the ocelli of the hindwing. Ground-colour light brown, hindwing distally yellowish. Under surface similar to *vindhya*, but with smaller eye-spots. Flies in March. April and July, neighbourhood of Nuwara Elya at about 5—6000 ft.

kansa. **L. kansa** *Moore*, originally described from Sikkim, comes with every consignment to Europe and is apparently equally at home in the hot valleys and at altitudes of 3000 m. *kansa* is one of the most simply marked species, above quite as uniform dark brown as beneath. Forewing without markings, hindwing with black ocelli of unequal size, which in Sikkim examples are distinctly margined with light yellow. In the Sikkim *zeugitana.* ♀ some indistinct yellowish patches are visible on the forewing. — **zeugitana** *subsp. nov.* (98 a as *kansa*), from Assam, is larger than the Sikkim *kansa*, altogether darker and the larger eye-spots of the hindwing are almost without yellowish bordering. Under surface brighter, red-brown bands more prominent, ocelli larger and more broadly margined with whitish violet. Assam, Manipur. Our figure agrees with *zeugitana*, whilst those of Stau- *vaga.* dinger and Moore distinctly represent the less highly coloured Sikkim form. — **vaga** *subsp. nov.*, collected by

me in Tenasserim at the end of the dry season at about 4000 ft., is smaller than *kansa kansa*, is above still paler brown, but beneath more sharply marked than the Sikkim race, and with the ground-colour almost white-grey. The ocelli of the hindwing are about midway between those of Sikkim and Assam ♂♂. Flies in May.

L. vindhya *Fldr.* (98 b) only differs above from the preceding in the ♀♀ showing an indistinct yellow- *vindhya.*
brown median longitudinal band. Shape of wings also somewhat more rounded, tails shorter, ocelli larger. — **dolopes** *Hew.* is the dry-season form of the species, recognizable by the lighter colouring of the under surface and by *dolopes.*
some of the ocelli being smaller. Very rare in Sikkim, Assam and Bhotan. Flies at elevations of about 1200 m. August, September. — **ladesta** *subsp. nov.* is likewise a small race, analagous to *kansa vaga* from the same district. *ladesta.*
Above with the ocelli scarcely half as large, under surface essentially darker than in *vindhya*. Eye-spots of the forewing absent, but hindwing with very distinct, although small, apical and anal ocelli. Tenasserim. Very rare, always only found singly.

L. serbonis *Hew.* (98 b), previously only known from Sikkim, received by me also from Bhotan in a form *serbonis.*
with somewhat darker under surface, is local and not very common; it is said to fly in the wet season, June to September, during which it is to be met with in dense forests at elevations of about 7—9000 ft. Upper surface uniform brown with slight bronzy reflection, ocelli of the under surface only showing through slightly, the anal one with distinct white pupil. Wings nearly quadrate, tails very short. A ♀ before me from Bhotan bears beneath very broad cocoa-brown areas and the submarginal band is twice as strongly developed as in the ♂♂. On the other hand the median brown longitudinal band of the forewing is absent in the ♀. — **davidi** *Oberth.* *davidi.*
(vol. 1, p. 83, pl. 30 b), in my collection from Mupin, is a geographical branch from West China, flying in June and July at about 8000 ft., whose relationship with *serbonis* Leech has already emphasized. **flavofasciata** *Leech* *flavofas-*
is probably the dry-season form of the ♀ of *davidi*. *ciata.*

L. sinorix *Hew.* (98 b) is a graceful species of elegant shape, easy to recognize by the sinuate forewing, *sinorix.*
the long, pointed tails and the broad, sharp, brown-red, almost rectilinear, parallel longitudinal bands of the under surface. Upper surface with three yellowish subapical patches on the forewing and a reddish, moderately extended submarginal area on the hindwing. Ocelli black, much larger than beneath. ♀ with the hindwing almost entirely light red and the yellowish longitudinal band of the forewing paler. *sinorix* is very constant, examples before me from Sikkim, Bhotan, Assam and Cachar do not vary at all. Very rare in Sikkim, it is more commonly taken in Bhotan. Flies from July to September. Dr. Manders found it also in Bernardmyo, Upper Burma, at 7000 ft.

L. samio *Dbl. & Hew.* is doubtless the Javan representative of the preceding species. Before my *samio.*
visit there, East India was recorded as its habitat. Even in Java very local and rare, occurring exclusively at Mt. Gedé at 4—6000 ft. It differs beneath chiefly in the elbowed, instead of straight distal band of the forewing. The ♂ is without the white, or more often yellowish subapical patches above, and the ♀ bears a very broad band on the forewing, composed of three longitudinal patches of unequal size.

L. satyavati *Nicév.* is beneath somewhat similar to *crijnana* (98 c) and with the ocelli of the same *satyavati.*
form, but without the white band of the forewing and of a pale grey-brown colour. Upper surface brown with the distal area but little lighter. Hindwing with small black dots in the ocelli, which show through from the underside. Only 2 ♀♀ known, which give quite the impression of an extreme dry-season form. Assam.

L. mekara is more widely distributed and much more variable than has been supposed. The species is more subject to seasonal dimorphism than the *Lethe* hitherto dealt with and almost always occurs together with *chandica Moore*. The two may easily be confused, especially as their dry-season forms are really very similar. But the under surface affords a safe distinguishing character in the distal band of the hindwing being but little excurved in *mekara*. — **mekara** *Moore* was described from Darjeeling, where it flies from the lower *mekara.*
valleys up to about 1500 m. from March to November in bamboo thickets, and when chased takes refuge among the foliage, when it is difficult to detect. Upper surface of the ♂♂ as in *crijnana*, except that the submarginal red on the hindwing is somewhat lighter and more extended. ♀ with light red upper surface to the wings and more extended white oblique band on the forewing, otherwise as in *sumati* ♀ (98 d), under surface similar to that of *crijnana* (98 c), but lighter and with much broader, glossy white median longitudinal bands. **vajra** *form.* *vajra.*
nov. is the unusually different spring generation (March, April), of which I have examples before me which show no markings at all on the underside of the wings and in which the uniform sand-brown ground bears only indistinct longitudinal bands. Together with it occurs an intermediate form, in which only the eye-spots are reduced, but distinct brown and whitish bands are still present. Moore also knew this form and figured it as the dry-season form of *mekara*. — **zuchara** *subsp. nov.* chiefly differs in the ♀ in the deep red-brown ground- *zuchara.*
colour of the upperside of the wings, the darker and more broadly brown median areas of the underside and their more conspicuous silvery whitish distal bordering. Moreover the ♂♂ are somewhat more richly coloured beneath and the spring generation does not produce such extremely small examples as in *mekara mekara*. Assam. — **crijnana** *subsp. nov.* (98 c), collected by me in Tonkin in August—September, forms a transition to the hitherto *crijnana.*
unnoticed Macromalayan races in the almost complete absence of the distal silvery bordering of the very narrow,

but dark brown median areas on both wings. Above the ♀ of *crijnana* resembles that of *sumati* (98 d), except that the bands of the forewing, which are broken up into three isolated patches, are not quite so narrow as in
gopaka. the Sumatran race. *crijnana* is probably distributed to Tenasserim. — **gopaka** *subsp. nov.* The submarginal region of the hindwing, above darker red-brown and smaller, is beneath easy to distinguish by the reduction of the red-brown median areas, in place of which the median whitish bordering of the red subbasal longitudinal
debata. band is considerably extended. Perak. Also reported from Salanga. — **debata** *subsp. nov.* (98 d), strange to say, is the albinotic extreme of the collective species: ♂ above with the subanal area of the hindwing somewhat less broad than in *sumati* ♂♂ (98 c) and the ♀♀ much paler, more yellow-red than *sumati* ♀♀ (98 d), but the under surface very washed-out, sandy grey-brown, of decided dry-form character and confusingly like the intermediate Indian *mekara*. ♀ beneath predominantly light yellow with dull brown longitudinal stripes and less pronounced whitish bands than *gopaka* ♀♀ from Perak. According to Martin *debata* is common everywhere in the alluvial plains where there are bamboo hedges, thus chiefly near villages and houses, but flies also on the spurs of the mountains. Examples from the last-named have the yellow-red colour on the upperside of the
sumati. hindwing more extended. — **sumati** *subsp. nov.* (98 c, d) is the furthest removed from the *mekara* type; ♂♂ recognizable at once by the extended light red submarginal area of the hindwing above, in which very commonly all the ocelli except the subanal disappear, and in the ♂ even the anal ocellus is also occasionally nearly obsolete. Under surface of the two sexes differing less from one another than in *gopaka*, also with less of the pure white, but marked with more intensive violet-grey. North Borneo, apparently not rare.

L. manthara doubtless represents *mekara* on Java and Bali, but is nevertheless entitled to specific rank, as is already shown by the vertical pointing of the grey-white band of the forewing, which is not obliquely placed in the anterior part as in *mekara*. The ♂♂, on the other hand, do not differ essentially either above or beneath from those of *debata* and *sumati*, although the disappearance of the red-brown bordering of the ocelli
manthara. has not advanced so far in the Macromalayan races. — **manthara** *Fldr.* (98 e) inhabits West Java at elevations of 2—5000 ft. and can be attracted with hung fruit. ♀ above nearly approaching that of *mangala* (98 e), but with more pronounced white-grey longitudinal band on the forewing and more extended light yellow-brown submarginal area. Beneath predominantly yellow-brown with light brown areas of fairly equal breadth, distally
mangala. somewhat darkened. Ocelli as in the ♂ almost uniformly filled up with violet. **mangala** *form. nov.* (98 e) is a dry-season form observed and collected only by myself in East Java, the ♀♀ of which have the under surface of a beautiful pale yellow tone, and entirely without brown bands. ♂ likewise without brown longitudinal areas, but as in *debata* and *sumati* with slight violet gloss in the median part. Elevations of 500—1000 m.

L. chandica, somewhat rarer than *mekara*, always occurs in India with the latter, at the same time and at the same altitudes. Somewhat more widely distributed than *mekara*, as it also extends into western China and to Formosa, and has spread from Luzon to Palawan. Like *mekara* it is very susceptible to local and
chandica. climatic influences and the result is a series of sharply differentiated local and island races. — **chandica** *Moore*, described from Darjeeling, is not very common in Sikkim, where it occurs from March (dry season) to October (end of the wet season) in the lower valleys. It is also reported from Assam and Manipur. Examples from Assam, however, stand in the same relation to the Sikkim type as *mekara zuchara* from the Khasia Hills to *mekara Moore*, i. e. they show a decided advance in the direction of melanism and a large series of ♂♂ in my collection differs from a similar series from Sikkim (as well as Moore's description and figure) in the more deeply coloured under surface adorned with darker brown. The ♀ is black-brown instead of red-brown at the base on the upperside of
flanona. the wings (= **flanona** *subsp. nov.*). — Further to the east, in Tonkin, the shape of the wings already differs and exam-
suvarna. ples from there (**suvarna** *subsp. nov.*) present a transition to *coelestis Leech* (vol. 1, p. 84, pl. 31 a), which has hitherto stood quite isolated. The rainy-season form does not differ essentially from *flanona* from Assam, on the other
rahula. hand the under surface of the ♂♂ in the dry-season form (= **rahula** *form. nov.*) has the colouring and the shape of the ocelli quite as in *coelestis* (vol. 1, pl. 31 a) and *ratnacri* (98 b). Moreover the ♀ closely approaches that of *coelestis*, from which it only differs in its smaller size, smaller eye-spots on the hindwing above, but larger ones on the hindwing
coelestis. beneath. Tonkin, Chiem Hoa, August—September, at about 800 m. — **coelestis** *Leech*, from Central and West China, observed by Leech also at Fuchow in southern China, shows, as is the rule in forms from the Celestial
ratnacri. Empire, a larger reproduction of the Indian *chandica*. — **ratnacri** *Fruhst.* (98 b) is a melanotic island race. Both sexes characterized by more rounded wings, shorter tails, ♂ above only with a very narrow red-brown distal line, ♀ dark red-brown with smaller ocelli on the hindwing above. Distal area on the underside of the hindwing extended, suffused with light chocolate-colour, and with a violet tinge round the ocelli, which is wanting in *coelestis*. Formosa, not very rare, especially in March and April near Kagi on the spurs of the mountains and
negrito. at the Lehiku Lake in the interior. Discovered by Herr Hans Sauter. — Under the name **negrito** *Fldr.* a whole series of heterogeneous island races are grouped together, but the name can only stand for the Luzon form, which occurs from May to August and then again from October to February. All the Philippine races approximate to

mekara Moore in the lighter or darker red-brown subanal area of the hindwing differing in breadth according to the locality. Most like it is probably **ratnapandi** *subsp. nov.*, which flies in January on Palawan and is very rare. Apart from the somewhat more rounded wings it is scarcely distinguishable above from *mekara debata Fruhst.* from Sumatra. ♀ above much lighter red-brown than even the Javan *marga* (98 c), but the white band on the forewing narrower, yet more compact, only the last intramedian spot separated. Anal angle of the forewing and costal part of the hindwing tinged with yellowish. Under surface of the ♂ about as in *ratnacri*, only the ocelli more uniformly round, but in colouring more approaching the Sikkim race. ♀ with beautiful yellow distal bordering to the brown median tooth of the longitudinal band of the hindwing. — **sisapon** *subsp. nov.* inhabits Mindoro; it is somewhat smaller than *negrito* from Luzon, but bears on the upperside of the hindwing the most intensively red tinge, the round, black ocelli being separated. — **byzaccus** *subsp. nov.* is the race from the island of Mindanao, where (judging from Semper's collection) two different seasonal forms occur, that of East Mindanao with a relatively large ♀, which has the band of the forewing still more divided than in *coelestis Leech* and even broken up into separate patches. On Mt. Sibulan, however, flies a smaller form with darker red anal border of the hindwing than in *sisapon*. — But the smallest race occurs on Jolo in the Sulu Archipelago: **jomaria** *subsp. nov.*, with much darker, reduced red anal area on the hindwing above, short, narrow white oblique band on the forewing of the ♀ and beneath with the deepest brown tinge. On Borneo *chandica* has yet to be discovered; there is no record from there at present. — **namura** *subsp. nov.*, from Sumatra and Perak, may best be described as a form of the Assam race with somewhat paler under surface, also differing from the Javan branch of *chandica* in the absence of the grey-violet tinge on the under surface; ♀ unknown to me, very rare. In 13 years Dr. Martin has only obtained one example from the Battak Plateau (North-East Sumatra). The ♀ bears a white transverse band on the forewing, which is very broad at the costa and is only once bent, and two indistinct apical spots. From West Sumatra (Padang Bovenland) in my collection. — Finally **marga** *subsp. nov.* (98 c) is the most differentiated island race, captured by me only at Mt. Gedé in West Java at about 12—1500 m., and very rare. The ♂, like the Sikkim *chandica*, bears very distinct yellow cilia on both wings, and the whole proximal side has a strong, glossy violet-grey tinge. Hindwing with a small but very dark brown spot inside the distal band, which is outcurved in the shape of a nose. ♀ above brilliant light red-brown, with yellowish costal border of the hindwing. In addition it bears on the forewing the broadest white subapical band of any of the known *chandica* branches.

ratnapandi. *sisapon.* *byzaccus.* *jomaria.* *namura.* *marga.*

L. distans *Btlr.* (98 c). An extraordinarily rare species, of which more ♀♀ than ♂♂ have been found, but relatively widely distributed, Bhotan, Sikkim, Assam and Burma. Details as to the habits of flight are not yet known. Moore thought that *distans* might probably be the spring generation of *chandica Moore*; an error which Nicéville has already refuted, for the dry-season form of *chandica* shows only very little of the red-brown shade on the hindwing above, and moreover Moore's type of *chandica* is actually based on the spring generation. For the rest the ♀ of *distans* has much more analogy with that of *mekara*, the band of the forewing being twice bent and broken up into separate patches and the upperside of both wings of a light yellow-red colour. The light grey upper surface of the forewing of the ♂♂, however, which is more suggestive of *L. kansa Moore*, is sufficient alone to differentiate *distans* from *chandica*.

distans.

L. delila *Stgr.*, above approaching *dora* (98 d), appears to replace *distans* on Borneo. The ♂ has above much more in common with *chandica* ♂♂, agreeing in the distal nose-shaped projection of the outer longitudinal band and the brown median spot on the hindwing beneath, but according to its author's diagnosis the ♀ bears a broad clay-yellow oblique band, which runs uninterrupted to the anal angle. Staudinger compares the ♀ of *delila* also with that of *darena*, which at once proves that this interesting species does not belong to the *chandica* group. Kina Balu and Marapok, North Borneo, at about 1000—1200 m.

delila.

L. dora *Stgr.* (♀ = cerama *Shelf.*) (98 d), of which we figure here for the first time the ♀, described by Shelford as *cerama*. The ♂ only differs above from the ♀ in the darker red-brown, more sharply defined anal area of the hindwing. Beneath both sexes are easy to distinguish from *delila* and *chandica* by the vertical submarginal band of the forewing, which borders a dark brown area as in *vindhya Fldr.* Very rare, type from South-East Borneo; has also been more recently discovered at Kuching in Sarawak.

dora.

L. perimede *Stgr.*, from Kina Balu. Only 2 ♂♂ known as yet. Size about the same as that of *L. europa F.*, which it somewhat resembles above, colour of the upper surface blackish brown, somewhat lighter than in *mekara sumati Fruhst.* Forewing with a sexual spot, which is placed beyond the cell and resembles that of the European *Satyrus* (*Pararge*) *maera L.*, extending from the upper median to the lower median near the cell-wall. Under surface of the forewing light grey-brown with dull steel-blue longitudinal bands, several ocelli and two anteterminal lines. Hindwing with six round eye-spots, which show white pupils. All the ocelli margined with brown-yellow. Behind the cell a glossy blue-green lunular spot and two median lines. The colouring of the under surface indicates affinity with *L. darena Fldr.*

perimede.

L. darena, the most richly coloured and most pronouncedly sexually dimorphic species of the genus, inhabits the Macromalayan region; already known from the three large Sunda Islands, its discovery on the Malay Peninsula will be only a question of the exploration of the mountainous regions, for it is only in these
sumatrensis. that this rare species seems at home. — **sumatrensis** *Stgr.* (98 d misprinted *sumatrana*) in the ♀ nearly approaches that of *borneensis* (98 e) and bears a broad yellow band, which becomes darker towards the hinder angle, shows a tendency to break up into round spots, and is proximally curved at the end. Forewing in addition with three light yellow subapical spots, of which the upper two are very small. Upper surface of the ♂ tinged with yellow-brown to beyond the cell. Locality the Battak Plateau in North-East Sumatra, where the species
borneensis. occurs all the year round. — **borneensis** *Stgr.* (98 e) differs from *sumatrensis* in the ♂ above in that the reddish ochre-coloured submarginal shading stops at the cell of the hindwing and does not enter it. The six wedge-shaped antemarginal patches of the forewing essentially larger, under surface differing considerably in the yellow subanal spot of the forewing being longer than broad and the longitudinal bands of the hindwing much broader and darker cocoa-brown. The much larger ocelli are placed in a lighter distal area and are margined with lighter yellow. ♀ beneath decidedly approaching the pattern and colouring of *chandica*, with the same median nose-shaped marking, which is distally covered with yellowish longitudinal stripes. Ground-colour reddish brown with grey-violet tinge. The oblique band of the forewing very broad beneath also and pale straw-
darena. yellow. The habitat of this most beautiful of all the *Lethe* is Mt. Kina Balu. — **darena** *Fldr.* ♂ analogous to *sumatrensis* in habitus and in the character of the colouring, but the submarginal light area on the upperside of the hindwing, as in *borneensis*, only extends to the cell-wall. Both wings beneath traversed by darker brown longitudinal bands, the ocelli more filled up with black and more distinctly white-pupilled. ♀ differing considerably from the two preceding races in the essentially narrower transverse band of the forewing, which is pure white on both surfaces, only extends to the submedian and before this has already a rounded patch separated off. Hindwing above lighter and brighter red-brown than in *borneensis* with beautiful yellow bordering to all the ocelli. Very rare on Java, found by me only in the west of the island, and there only on Mt. Gedé.

c) With sexual spots on the upperside of the hindwing.

christophi. **L. christophi** *Leech*, hitherto only known from Omishan in West China, was discovered by my collector in Formosa, so that there are now two races to register: *christophi Leech* (vol. 1, b. 83, pl. 29 e), with very large
hanako. glossy sexual spot on the hindwing, flying in July and August; and **hanako** *Fruhst.* (98 e), with somewhat smaller scent-area on the hindwing and beneath larger ocelli and stronger longitudinal bands. Flies in September and October, at about 4000 ft. Formosa.

mataja. **L. mataja** *Fruhst.* (99 a), a completely isolated species without near allies and easy to recognize by the almost deep black ground-colour, a white oblique band on the forewing running as in *verma Koll.* and a tuft of long, black, glossy hairs on the upperside of the hindwing, set between the middle and lower medians. Hindwing with the ocelli showing through from the underside. Under surface: black-brown, band somewhat widened, purer white than above. Three subapical ocelli, of which the anterior is the smallest. Hindwing with a row of 5 ocelli, of which the upper four are placed close together, whilst between the fourth and the bi-pupilled ocellus there is a large space, as the area between the middle and lower medians remains free, i. e. encloses no eye-spot. Both the wings are traversed by a thin brown antemarginal and a broader, light grey submarginal band. The forewing bears two longitudinal bands in the cell, the hindwing a fairly straight subbasal band and a sharply angled median band. At the apex of the cell there is further a light-dotted streak. All these bands are dark brown. The yellow-ringed ocelli show also a pale violet-grey border. Upper surface of the hindwing below the ocelli with a long tuft of deep black, glossy radiating hairs, in which *mataja* differs from all its allies of the *lanaris-baucis-naga* group. ♀ somewhat larger, paler than the ♂, the white band of the forewing about twice as broad. Under surface paler with somewhat larger ocelli. Rare on Formosa. Type from the Drachen Lake, afterwards received also from Polisha and Lehiku. Flies in September and October.

L. sicelis Hew. (vol. 1, p. 84, pl. 31 b) inhabits the main island of Japan, whilst on the southern island
