Yli-Mattila, T. & J. Hyvönen (1996). RAPD-PCR analysis of *Fusarium* strains - cladistic evaluation of the results. – Sydowia 48(2): 184–195.

Cladistic analysis of 42 strains of *Fusarium* is presented based on data obtained with RAPD-PCR analysis using four primers. The six species included in the analysis were *F. avenaceum*, *F. culmorum*, *F. equiseti*, *F. graminearum*, *F. oxysporum* and *F. redolens*. All of the specimens were collected in Finland, primarily from barley, wheat and oats. The results of the cladistic analysis are only partly in accordance with the distinction of the taxa based on morphology. Different strains of *F. avenaceum* were not clearly distinguished from each other except for five strains that consistently formed two separate clades.

Keywords: cladistics, *Fusarium*, phylogeny, RAPD-PCR.

The genus *Fusarium* comprises species of fungi that are saprobes, weak parasites or endophytes under native field conditions. A number of species are commercially important as food contaminants or as parasites that cause vascular wilt diseases which have fostered interest on the taxonomy of the genus (Booth, 1971; Gerlach & Nirenberg, 1982; Bruns & al., 1991; Nelson, 1991; Nelson & al., 1983; Windels, 1991). Because of the limited number and variety of classical morphological characteristics available in the genus, molecular characters are probably more important in *Fusarium* systematics than in other fungi in which more informative morphological characters are available. Studies on strains or species of *Fusarium*, where new molecular methods have been used are exemplified by Kistler & al. (1987), Guadet & al. (1989), Nicholson & al. (1993), Assigbetse & al. (1994), and Yli-Mattila & al. (1996). In addition to molecular methods, vegetative compatibility tests can be used to distinguish different strains of the same *Fusarium* species (Correll, 1991; Gordon & Okamoto, 1992a; 1992b; Bridge & al., 1993; Leslie, 1993; Manicom & Baayen, 1993; Mes

& al., 1994). Our objectives were: (1) to determine the phylogenetic relationships of a set of strains of *F. avenaceum*, and (2) to determine whether strains of different species of the genus can be consistently distinguished as monophyletic groups based on the results of RAPD-PCR analysis.

Material and methods

RAPD-PCR analysis with four primers (91,299, 91,300, X and Y; Yli-Mattila & al., 1996) of 49 *Fusarium* strains collected in Finland (Tab. 1) provided a data matrix of 125 characters, of which 103 were informative (i.e. excluding constant and autapomorphic characters) for the cladistic analysis (Tab. 2). Characterization of the strains, plus methods of DNA extraction, amplification and electrophoresis are described by Yli-Mattila & al. (1996). Amplification was repeated 2–3 times for each sample, each amplification product was run at least twice on agarose gel and only reproducible results were accepted for the final data matrix. Bands were detected visually from photographs of the gels and recorded as present or absent (1/0) for the data matrix.

The six species included in the analysis were *F. avenaceum, F. culmorum, F. equiseti, F. graminearum, F. oxysporum,* and *F. redolens* (= *F. oxysporum* var. *redolens*). All strains of *F. avenaceum* used in the analysis were collected from barley, wheat or oats (Tab. 1). The other species of *Fusarium* were also collected from cereals, except for one strain of *F. oxysporum*, which was recovered from tomato (Tab. 1). The identification of the strains based on morphology according to Booth (1971) and Gerlach & Nirenberg (1982) was provided by Dr. A. Hannukkala of the Agricultural Research Centre of Finland.

Cladistic analyses of the matrices were made with the programs Hennig86 (Farris, 1988) and PAUP 3.1.1 (Swofford, 1993). The credibility of the results was examined using the program RNA by Farris (1994).

Tab. 1. – List of *Fusarium* strains. Isolate numbers are the stock numbers of strains in the collection of the Agricultural Research Centre of Finland.

Results

The initial analysis was carried out using two options from Hennig86: mhennig*, which contructs preliminary cladograms by adding the taxa in several different orders and retains the shortest cladogram for each sequence and bb*, branch-breaker, which generates multiple equally parsimonious trees. This analysis with 42 strains including only those strains of *F. avenaceum* collected on barley, wheat and oats gave the most parsimonious tree with the length of 346 steps (consistency index 0.347, retention index 0.707, Farris 1989). The large size of the data set made it impossible to use algorithms that ensured that all of the most parsimonious trees were found, so 30 random trees

were used as starting points for heuristic searches with the program PAUP 3.1.1. In addition to the tree found in the initial search by Hennig 86, another group (island) with two equally parsimonious trees was identified. A semistrict (combinable component, Bremer 1990) consensus tree is presented in Fig. 1. Another search with 50 replicates of random addition sequence of PAUP did not identify any other equally parsimonious trees.

When seven strains of *F. avenaceum* from hosts other than barley, wheat and oats were added to the matrix, the number of equally parsimonious solutions inflated to 156. A semistrict consensus tree is presented in Fig. 2. Basically the structure is the same as in the tree without these taxa, but with less resolution within the large *F. avenaceum* clade.

Discussion

Every cladogram includes several, frequently conflicting statements about the evolution of the characters, so it is advisable to explore the degree of support for individual branches. The first method for this evaluation was to count the number of characters that supported a particular node. However, as discussed by Sanderson (1989) this measure is not straightforward and actually cannot be used as a criterion to measure robustness of the individual clades. The interdependence of all characters of the data matrix can strongly affect the cladistic analysis and credibility of the results as discussed by Davis & al. (1993). Two methods were used to test the reliability of the trees that were generated.

In addition to the most parsimonious trees, it is also advisable to examine trees that are longer. This is done by constructing the strict consensus tree of all trees one step longer than the most parsimonious one(s), then two steps longer, etc. (Bremer, 1988). The number of extra steps, at which the support for the clade disappears, is its Bremer or branch support (Farris & al., 1994) or decay index (Donoghue & al., 1992; Graham & al., 1991). Calculation of the exact indeces larger than 2–3 for even moderate size matrices, however, exceeds the capabilities of most currently available computers and programs. To circumvent this problem an approximate support tree was calculated with the RNA-program by Farris (1994). Although this tree is different from the consensus tree it does include information of the support of the most consistent groups. The support for almost all the clades within *F. avenaceum* is very weak except for the clade including strains a17, a19, a37 and a50 and for the clade including strain 43. On the other hand values for each species, especially those of *F. culmorum, F. equiseti* and *F. redolens* are very high, supporting monophyly of the strains that are thought to belong to separate species on the basis of their morphology. The monophyly of the strains in each

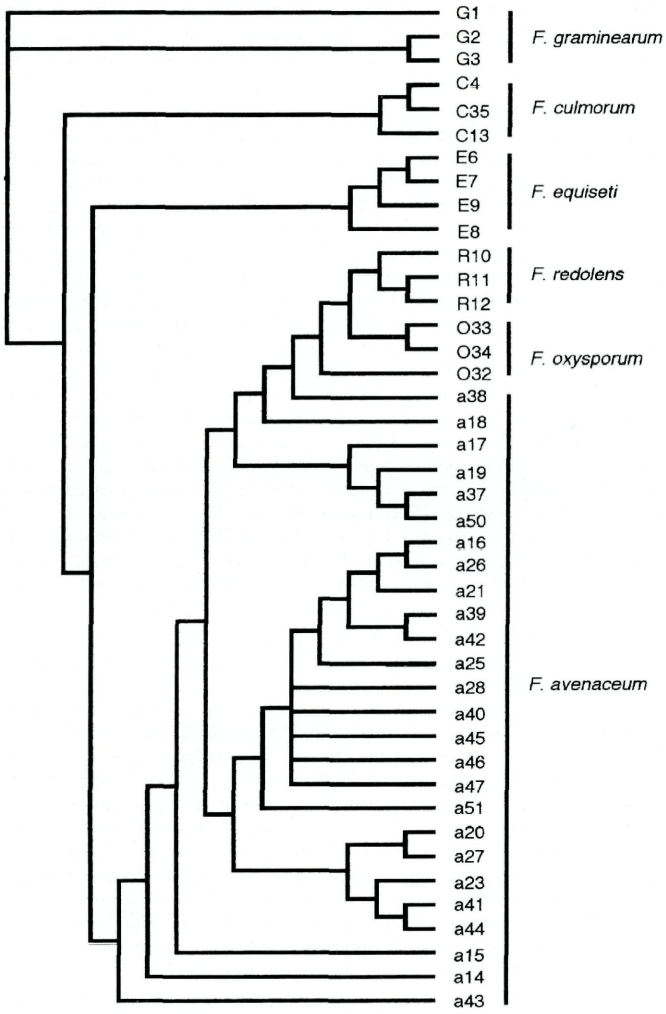

Fig. 1. – The semistrict consensus tree of three equally parsimonious trees for 42 strains of *Fusarium*. Strains marked with a are *F. avenaceum*, with c *F. culmorum*, with e *F. equiseti*, with o *F. oxysporum* and with r *F. redolens*.

species and the clear differences between strains a17, a19, a37, a50 and a43 as compared to other *F. avenaceum* strains are in accordance with the phenetic analysis of the same RAPD-PCR data (Yli-Mattila & al., 1996).

Bootstrapping (Felsenstein, 1985) was originally presented as a means to test the repeatability of the cladistic analyses (Hillis & Bull, 1993). This process works only if the distribution of the characters in the original data set is a good approximation of the distribution of the underlying character universe (Sanderson, 1989). In bootstrapping, a new data matrix is formed by randomly choosing characters from the original matrix with replacement. Accordingly, some of the original characters will not be included at all in the new matrix and some others will be represented by two, three or even more identical replicates. This procedure is repeated a predetermined number of times, and the majority rule (Margush & McMorris, 1981) consensus tree is constructed from the trees resulting from each replication. Support for each clade is given as the percentage of trees in which the particular clade is found. As noted already by Felsenstein (1985) and discussed in detail by Sanderson (1989), bootstrapping in practice identifies only the most unambiguous parts of the tree, as usually there is little statistical support for many of the clades found in the most parsimonious solutions because of character conflict. As can be seen in Fig. 3 on a approximate support tree, the clades with higher bootstrap values usually have also a higher Bremer support. The support values calculated with the program RNA (Farris, 1994) are based on 10,000 samples with replacement from the original data set.

The reliability of the RAPD-PCR results and their suitability for the phylogenetic analysis has been questioned because of the uncertain homology of the bands (Adams & Demeke, 1993; Hillis, 1994). Whether the problem of homology is more severe than with other kind of data has not, however, been proved, and RAPD-PCR results have been used also in phylogenetic studies of closely related species of flowering plants as exemplified by Buren & al. (1994). At least in the present material, the groups that are present in the cladogram are partly congruent with earlier taxonomic conclusions that were based on morphological characters, i.e. strains of the same taxa clustered together. However, it should be noted that the strains of both *F. oxysporum* and *F. redolens* are nested within the large *F. avenaceum* clade. The reliability of the RAPD results would be ideally tested by comparing the congruence (Farris & al., 1994) of different data sets obtained with different methods from the same strains.

In all cladograms presented, the strain a43 was revealed to be distinct from other strains of *F. avenaceum*. This is in accordance with the hybridization analysis of the UP-PCR amplification products (T. Yli-Mattila, N.V. Mironenko, I.A. Alekhina, A. Hannukkala &

S.A. Bulat; unpublished results, manuscript submitted) and by the preliminary rDNA RFLP study (Yli-Mattila & Paavanen-Huhtala, 1996).

In their morphological studies Nelson & al. (1983) and Baayen & Gams (1988) regarded *F. redolens* conspecific with *F. oxysporum*,

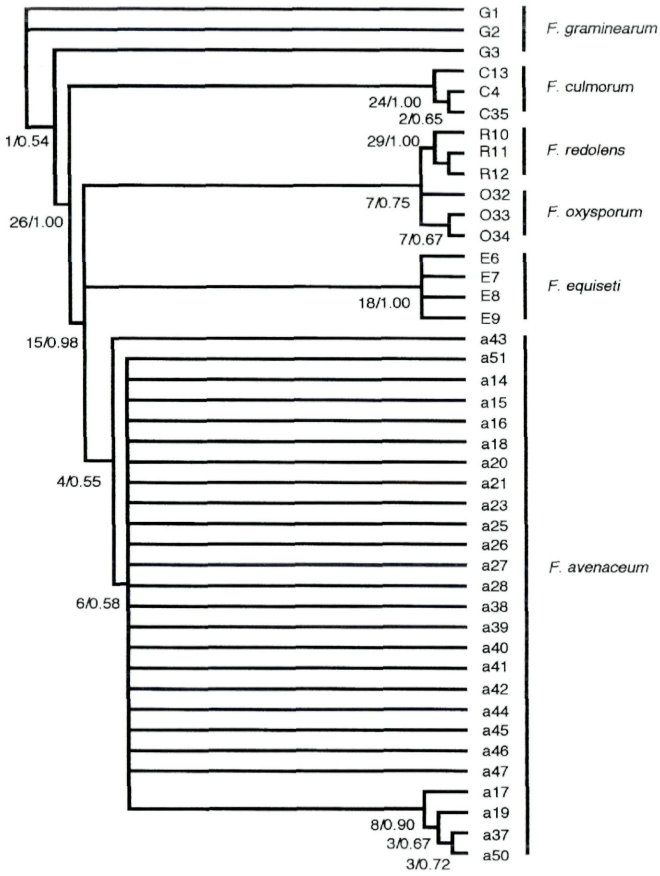

Fig. 3. – Approximate support tree calculated with the program RNA (Farris, 1994) showing branch support (the first number) and bootstrap (the second number, ≥ 0.50) indeces for the clades.

while Gerlach & Nirenberg (1982) considered them as distinct species. The latter view is supported by the rDNA RFLP study of Waalwijk & Baayen (1995). In the approximate support tree of the present study, the strains of all species, except the strain o32 of *F. oxysporum*, for-

med monophyletic groups with high branch support and bootstrap values. Isozyme and RAPD-PCR analyses of more *F. oxysporum* strains from Finland revealed that the strain o32 was only distantly related to other strains of *F. oxysporum* (Paavanen-Huhtala, 1995). This was also supported by the preliminary rDNA RFLP study (Yli-Mattila & Paavanen-Huhtala, 1996) which showed the strain o32 to be more closely related to *F. redolens* than other strains of *F. oxysporum*. Accordingly, the specific status of this strain remains doubtful.

The suitability of cladistic methods for studies below certain taxonomic level has been challenged (e.g. Wheeler & Nixon, 1990). However, as pointed out by Vrana & Wheeler (1992) there is no reason for *a priori* assumptions to be made about the level at which the use of cladistic methods is appropriate. Conclusions about the appropriateness of the results can only be drawn after the analysis is complete. For example, it is not surprising that the large *F. avenaceum* clade is fairly poorly resolved, since it might simply be that there is no hierarchic signal, no differentiated lineages, to be found in the strains of the same taxon collected from a fairly small area. Whether this hypothesis is true in this case can be confirmed only after more thorough analysis including other methods of data retrieval, e.g. direct sequencing.
